I. INTRODUCCION.

La definición de la serie de caudales en la toma del Canal Cambronal constituye un aspecto esencial en la determinación del potencial de riego del sistema en estudio.

Debido a la ausencia de una serie continua de caudales registrados en el río Majagual y en los ríos ubicados en sus cercanías, y no existiendo datos de la lluvia y evaporación que ocurren sobre el área de la cuenca, se hizo necesario un análisis regional que permitiera la transposición de los datos de lluvia y evapotranspiración existentes a dicha área.

Posteriormente, con las estimaciones de estas dos variables climáticas se procedió a obtener una serie de caudales reconstruidos, mediante un modelo lluvia-escorrentía del tipo determinístico.

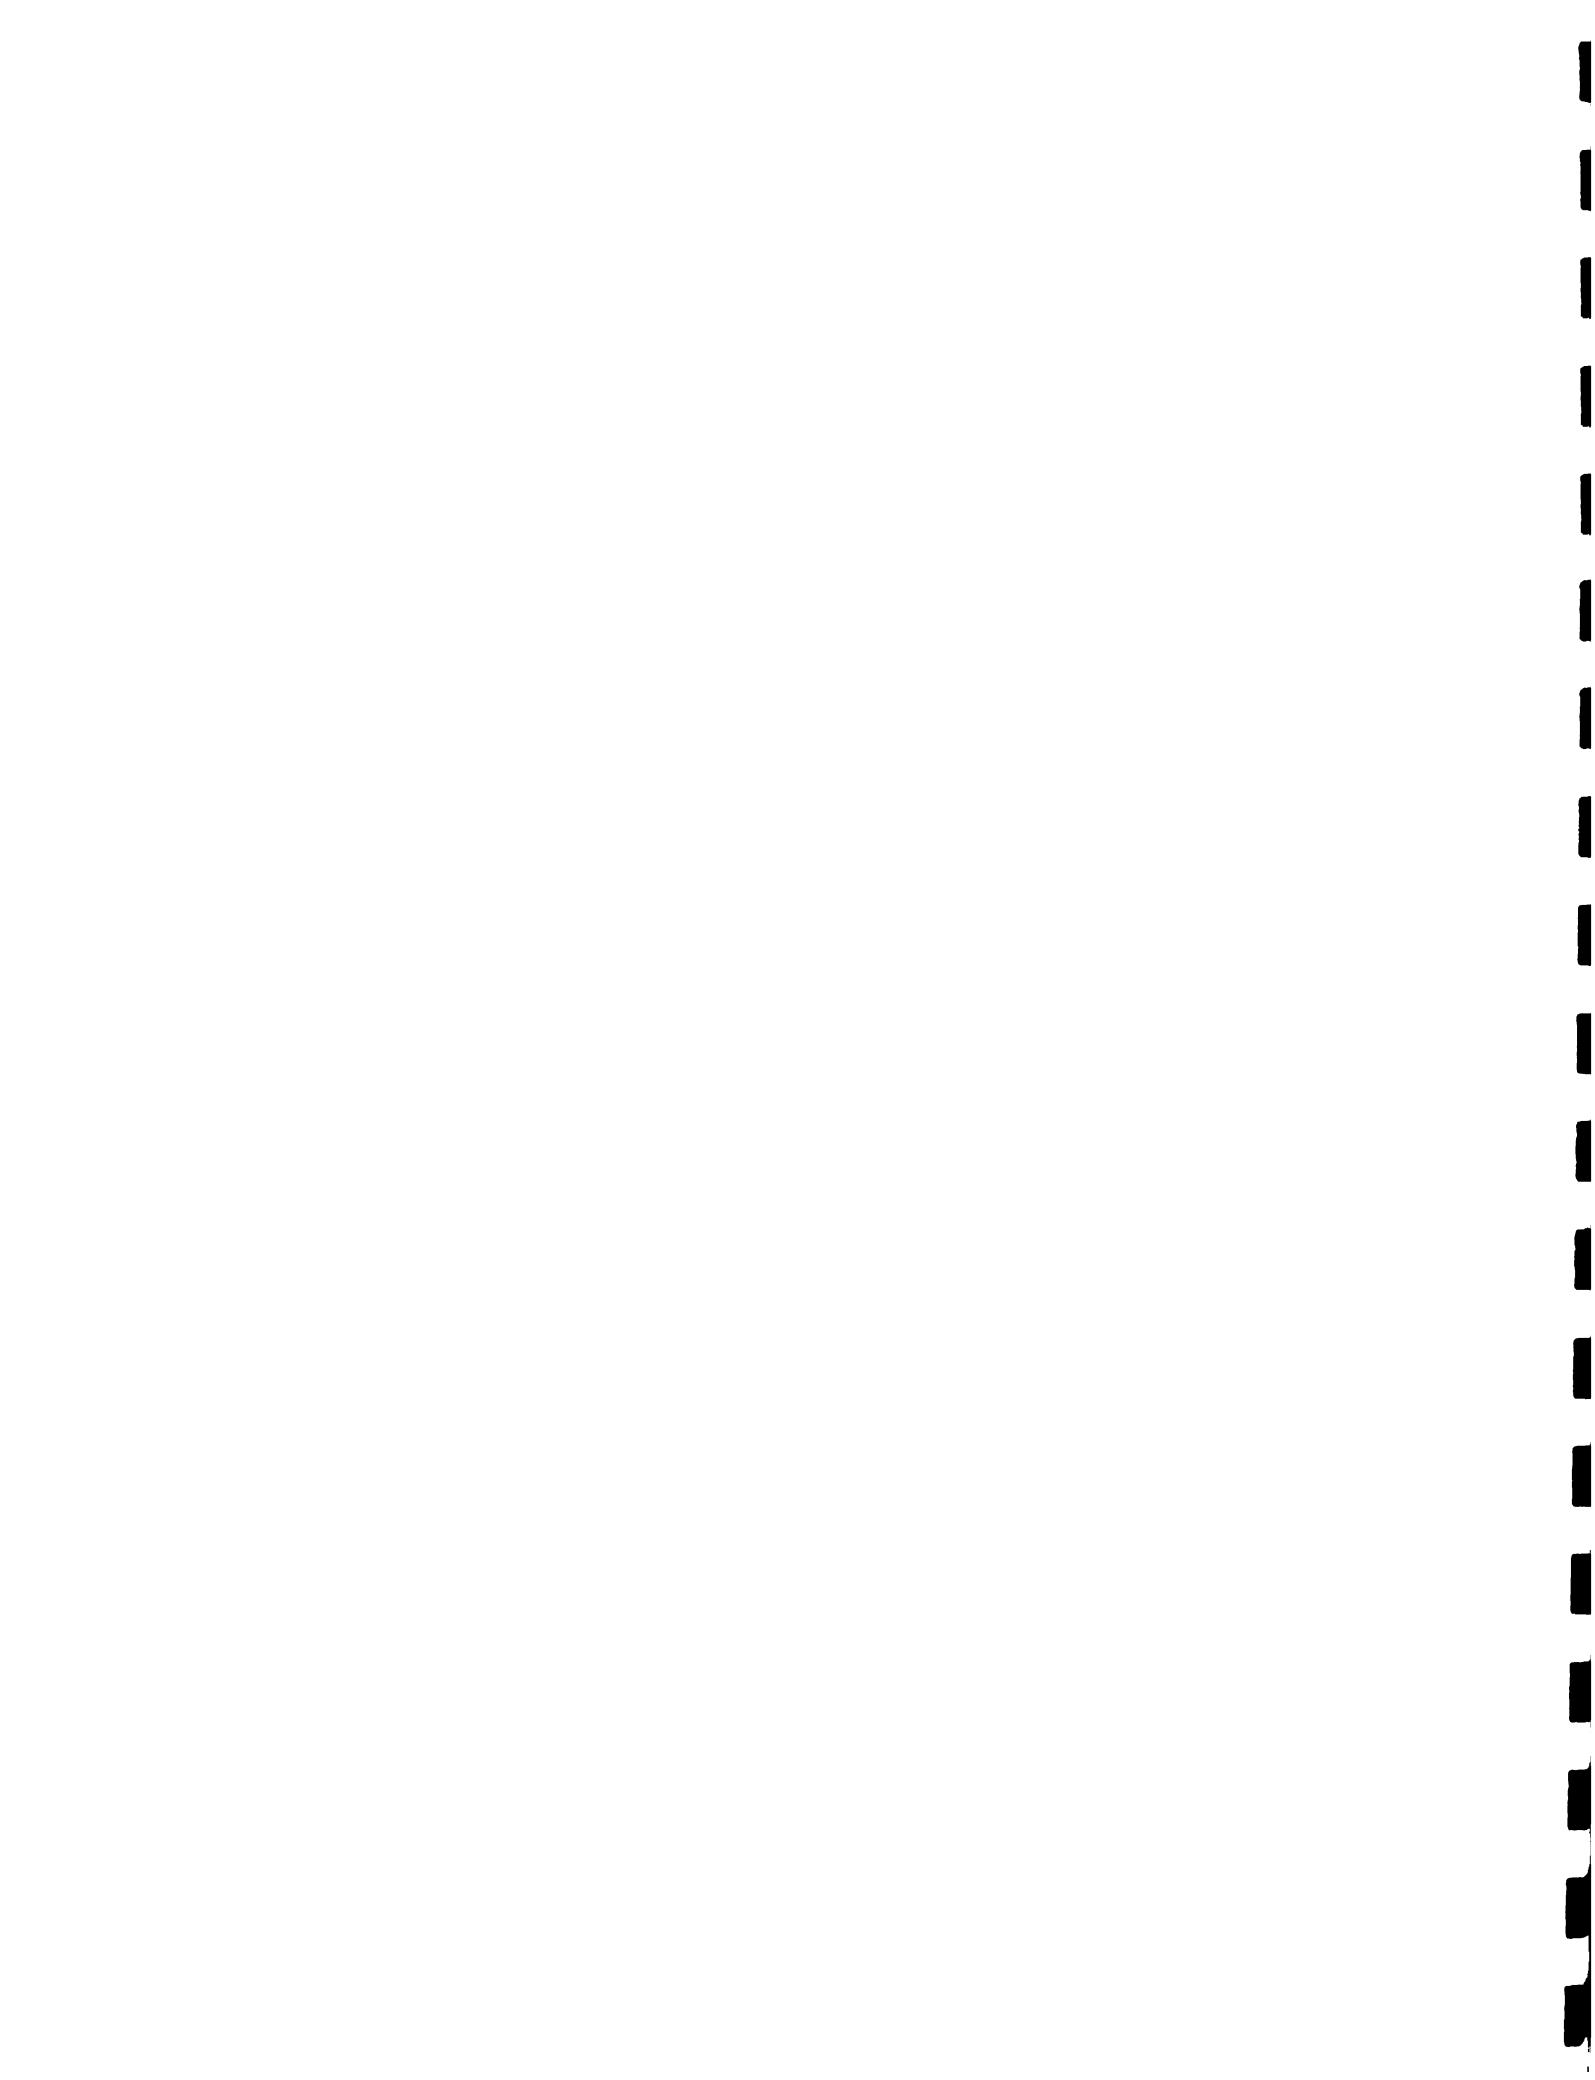

II. GEOMORFOLOGIA

1. Geología e Hidrogeología.

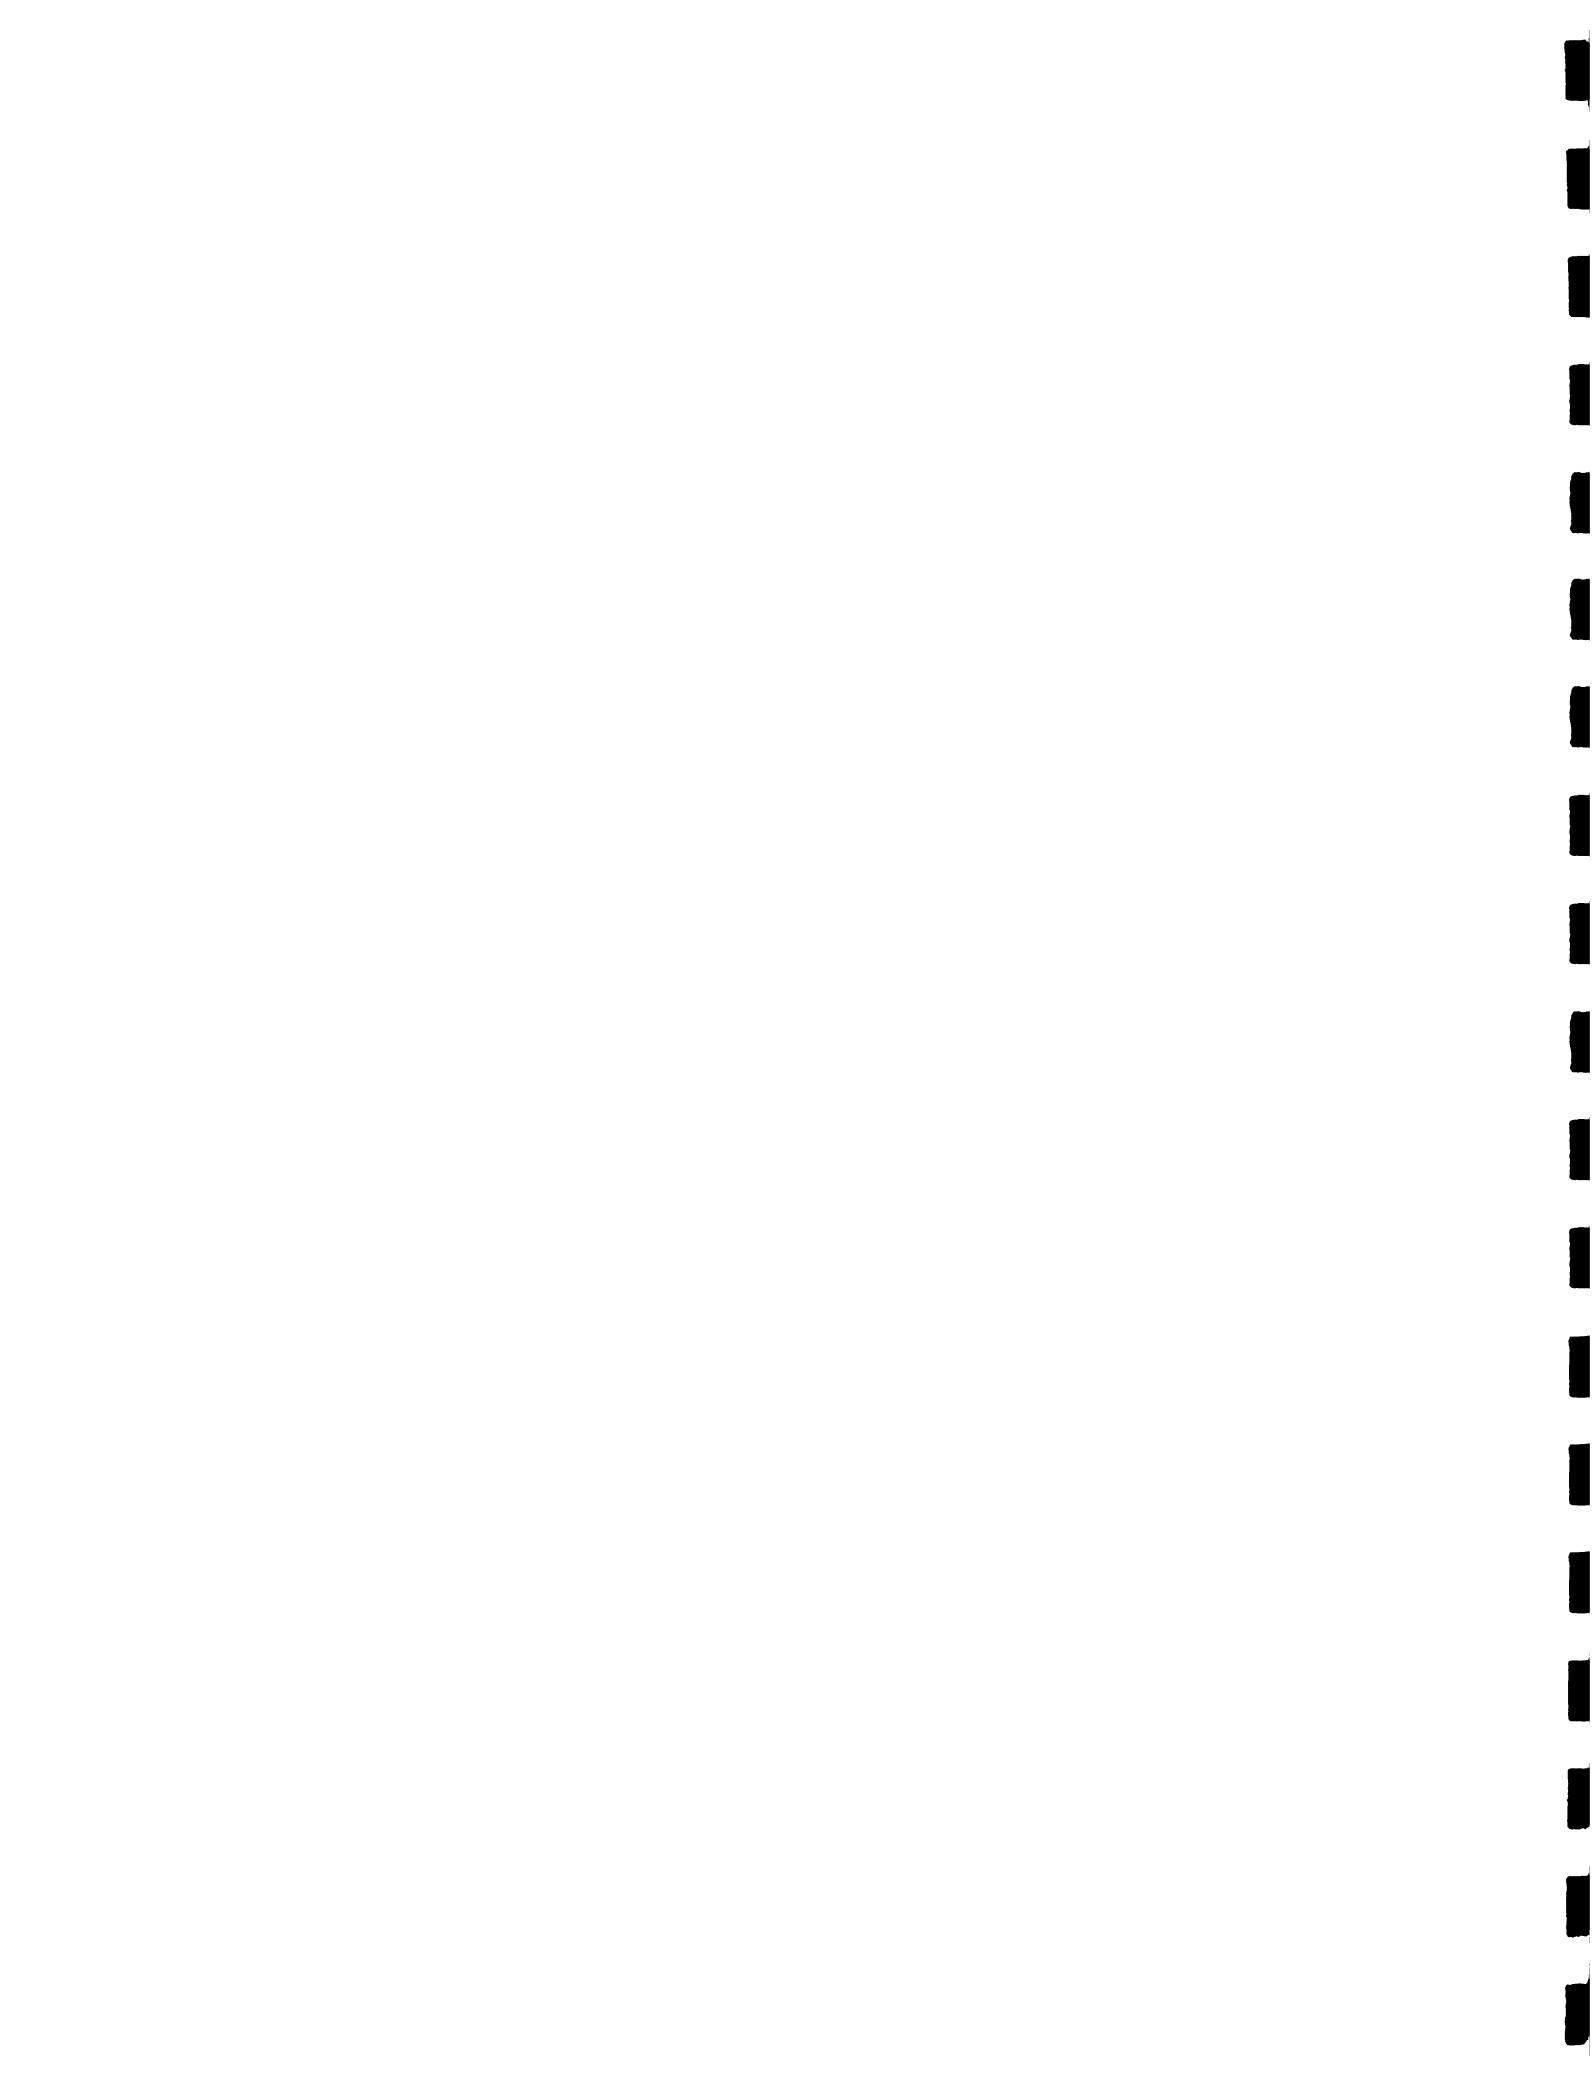

Tomando como base las características hidrológicas de las diferentes formaciones geológicas existentes en la región y en el área de la cuenca, las cuales se describen en el capítulo "Hidrogeología", así como las observaciones realizadas en el campo, se puede inducir que el estrato superior (abanco aluvial) posee una alta permeabilidad y tiene como piso una formación prácticamente impermeable (formación trinchera). Esta configuración hidrogeológica permite el establecimiento del flujo permanente del río Majagual y al considerar lluvias estimadas por encima de los 1,400 mm/año cabe suponer un flujo base muy estable, ya que los estratos permeables actúan como un embalse natural. Este tipo de respuesta ha sido confirmado por los aforos que se han realizado en el sitio de El Millo y por el testimonio de los moradores de la zona.

En un informe publicado por el Instituto Nacional de Recursos Hídricos (INDRHI) (1985), se presentan los primeros resultados de las investigaciones realizadas mediante la medición de la concentración de algunos isótopos presentes en las aguas de la región. En lo que respecta a la cuenca del río Majagual, se establece que la descarga de agua subterránea parece tener una componente importante hacia el este en la dirección

/...

Los Guineos- Neyba- Galván. Como se verá más adelante,
esta última conclusión tiene gran relevancia para los -
fines del presente estudio.

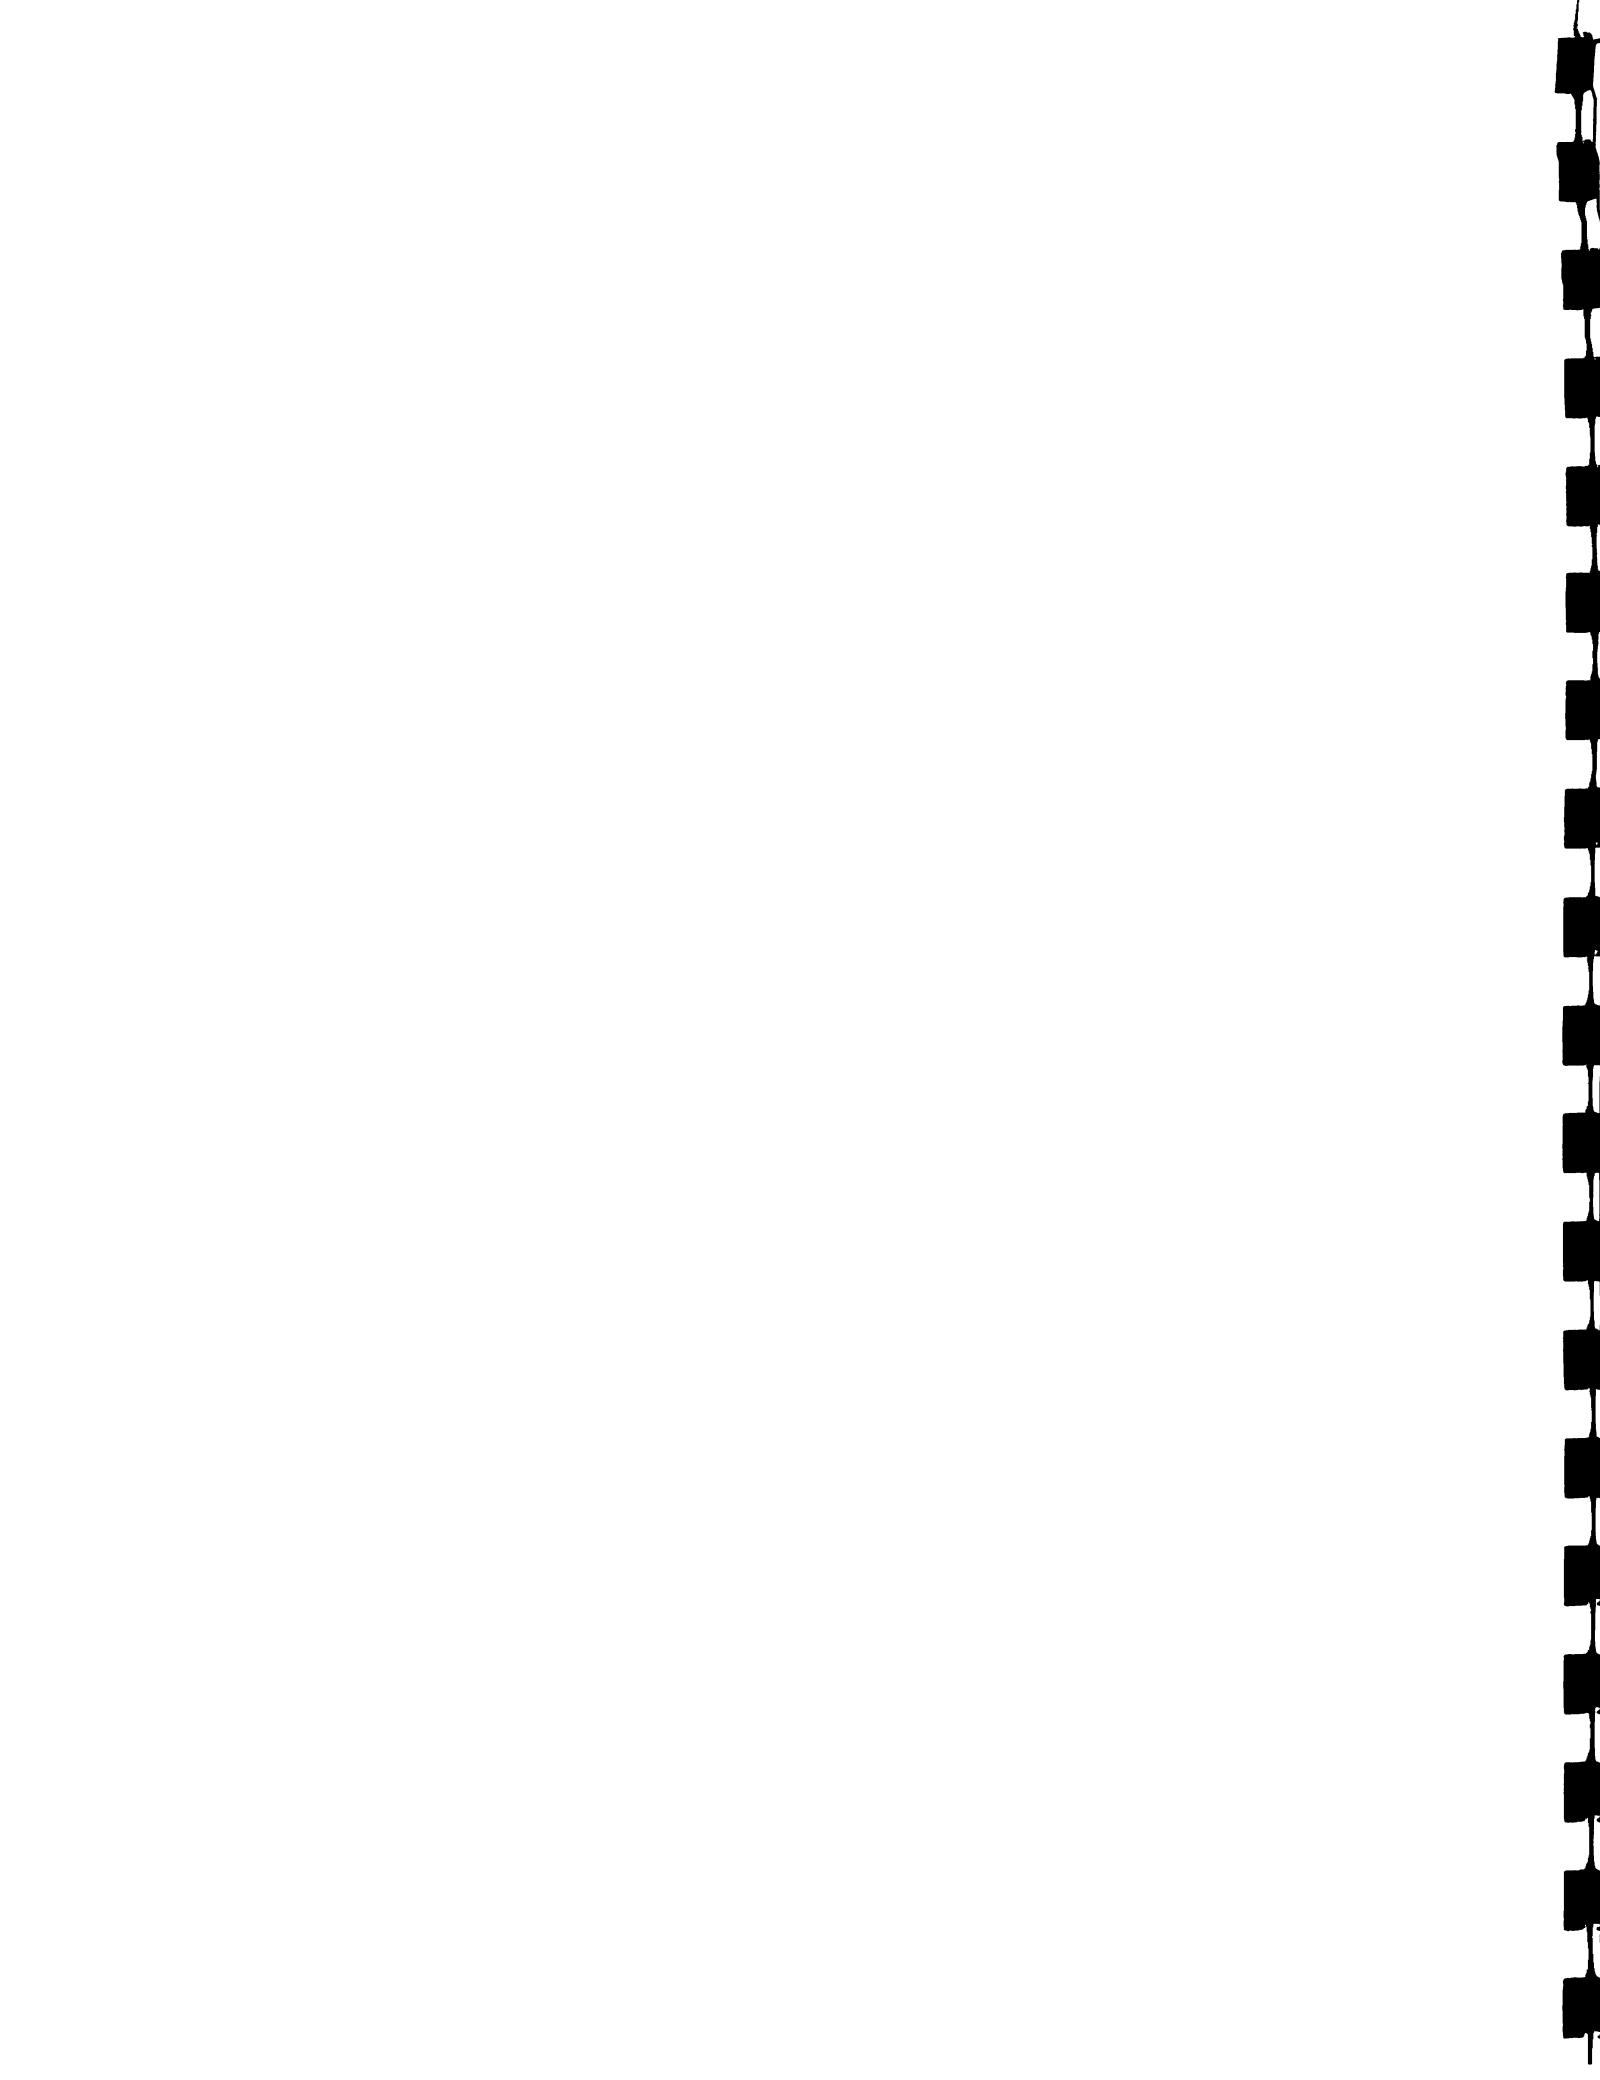

2. Geomorfología.

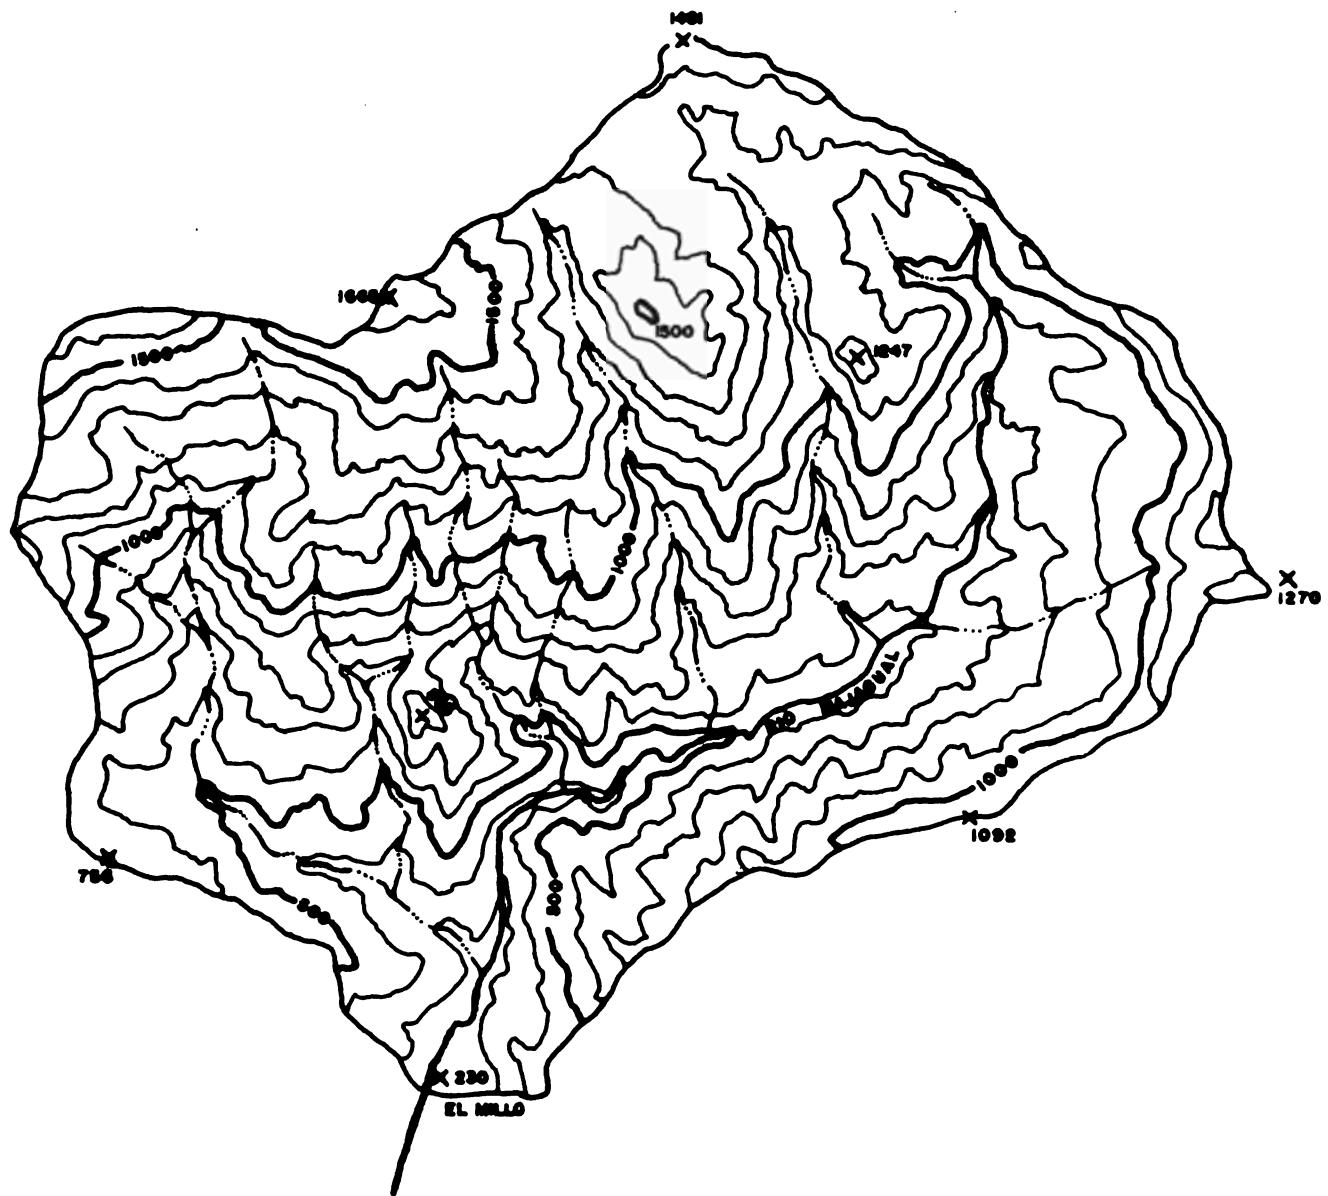

En el Mapa 1 se muestra el área de la cuenca y la red de drenaje del río Majagual hasta El Millo, tomado de la carta 1:50,000 del Instituto Geográfico Universitario. A partir de este mapa se determinaron los parámetros geomorfológicos más relevantes de la cuenca, los cuales se resumen a continuación:

| | |
|--|-------------------------|
| - Área superficial: | 36.45 Km ² |
| - Longitud de cauces: | 36.8 Km. |
| - Orden de la red de drenaje: | 4 |
| - Densidad de Drenaje: | 1.05 Km/Km ² |
| - Longitud de Escurrimiento Superficial: | 472.00 m |
| - Pendiente media del cauce principal: | 0.083 |
| - Pendiente media de la cuenca: | 0.524 |
| - Coeficiente de Bifurcación: | 2.0 - 3.25 |
| - Factor de Forma: | 0.728 |

El reducido valor de la densidad de drenaje, y el valor alto de la longitud de escurrimiento superficial son indicadores de la alta permeabilidad de la cuenca, mientras que los valores de la pendiente del cauce

EN MILLO
ESCALA 1:50,000

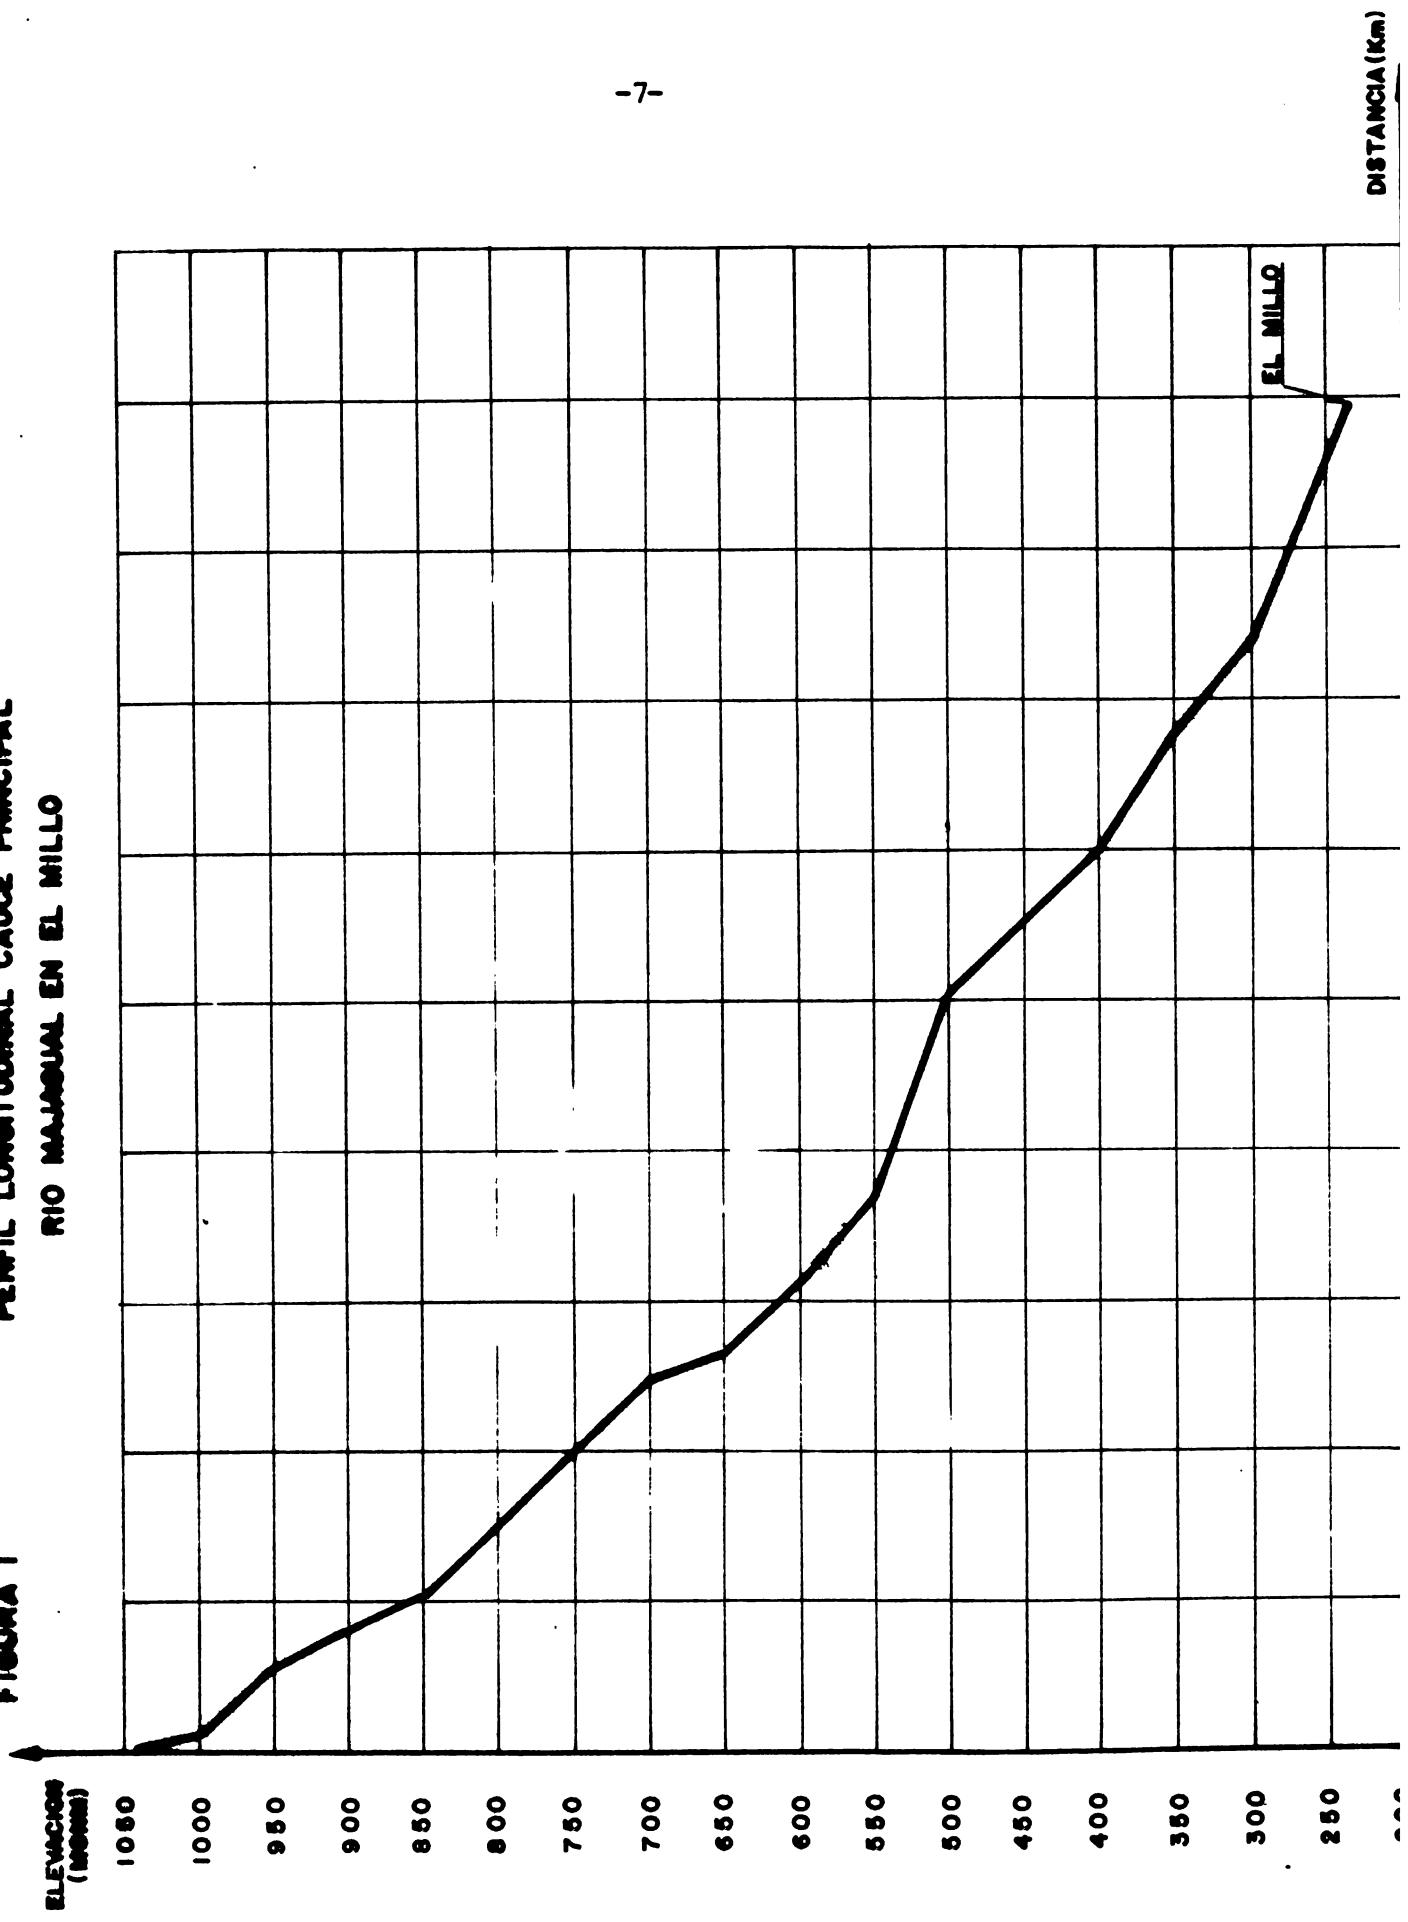

principal y de la cuenca, el coeficiente de bifurcación y el factor de forma determinan la capacidad de la cuenca para drenar con relativa rapidez el escurrimiento superficial, cuando está disponible.

En la Figura 1 se muestra el perfil longitudinal del cauce principal. La curva hipsométrica de la Figura 2 corresponde básicamente a una cuenca en estado de equilibrio o madurez, según Strahler (1964).

RIO MAJAGUAL EN EL MILLO

III. CLIMATOLOGIA.

A partir de que no existía información climática en el área de la cuenca, se procedió a examinar los datos existentes en la región, con el propósito de hacer la extrapolación a la cuenca del río Majagual en El Millo. Los registros de datos climáticos más cercanos al área de la cuenca son los correspondientes a la estación operada por el INDHRHI en Neyba, durante el período enero 1968- noviembre 1980. Adicionalmente, existen varias estaciones cuyos datos de lluvia y dirección del viento también fueron considerados. El Cuadro 1 muestra el tipo y longitud de los registros de lluvia disponibles.

1. Dirección y Velocidad del Viento.

Los datos de la velocidad del viento registrada en Neyba son resumidos en el Cuadro 2. Dada la diferencia de condiciones entre la cuenca y Neyba, se juzgó relevante considerar los registros de dirección y velocidad del viento en la estación de Barahona para con ellos establecer un patrón preliminar de la circulación regional, como discute en la sección III.4 Estos datos se muestran en los Cuadros 3 y 4.

2. Temperatura.

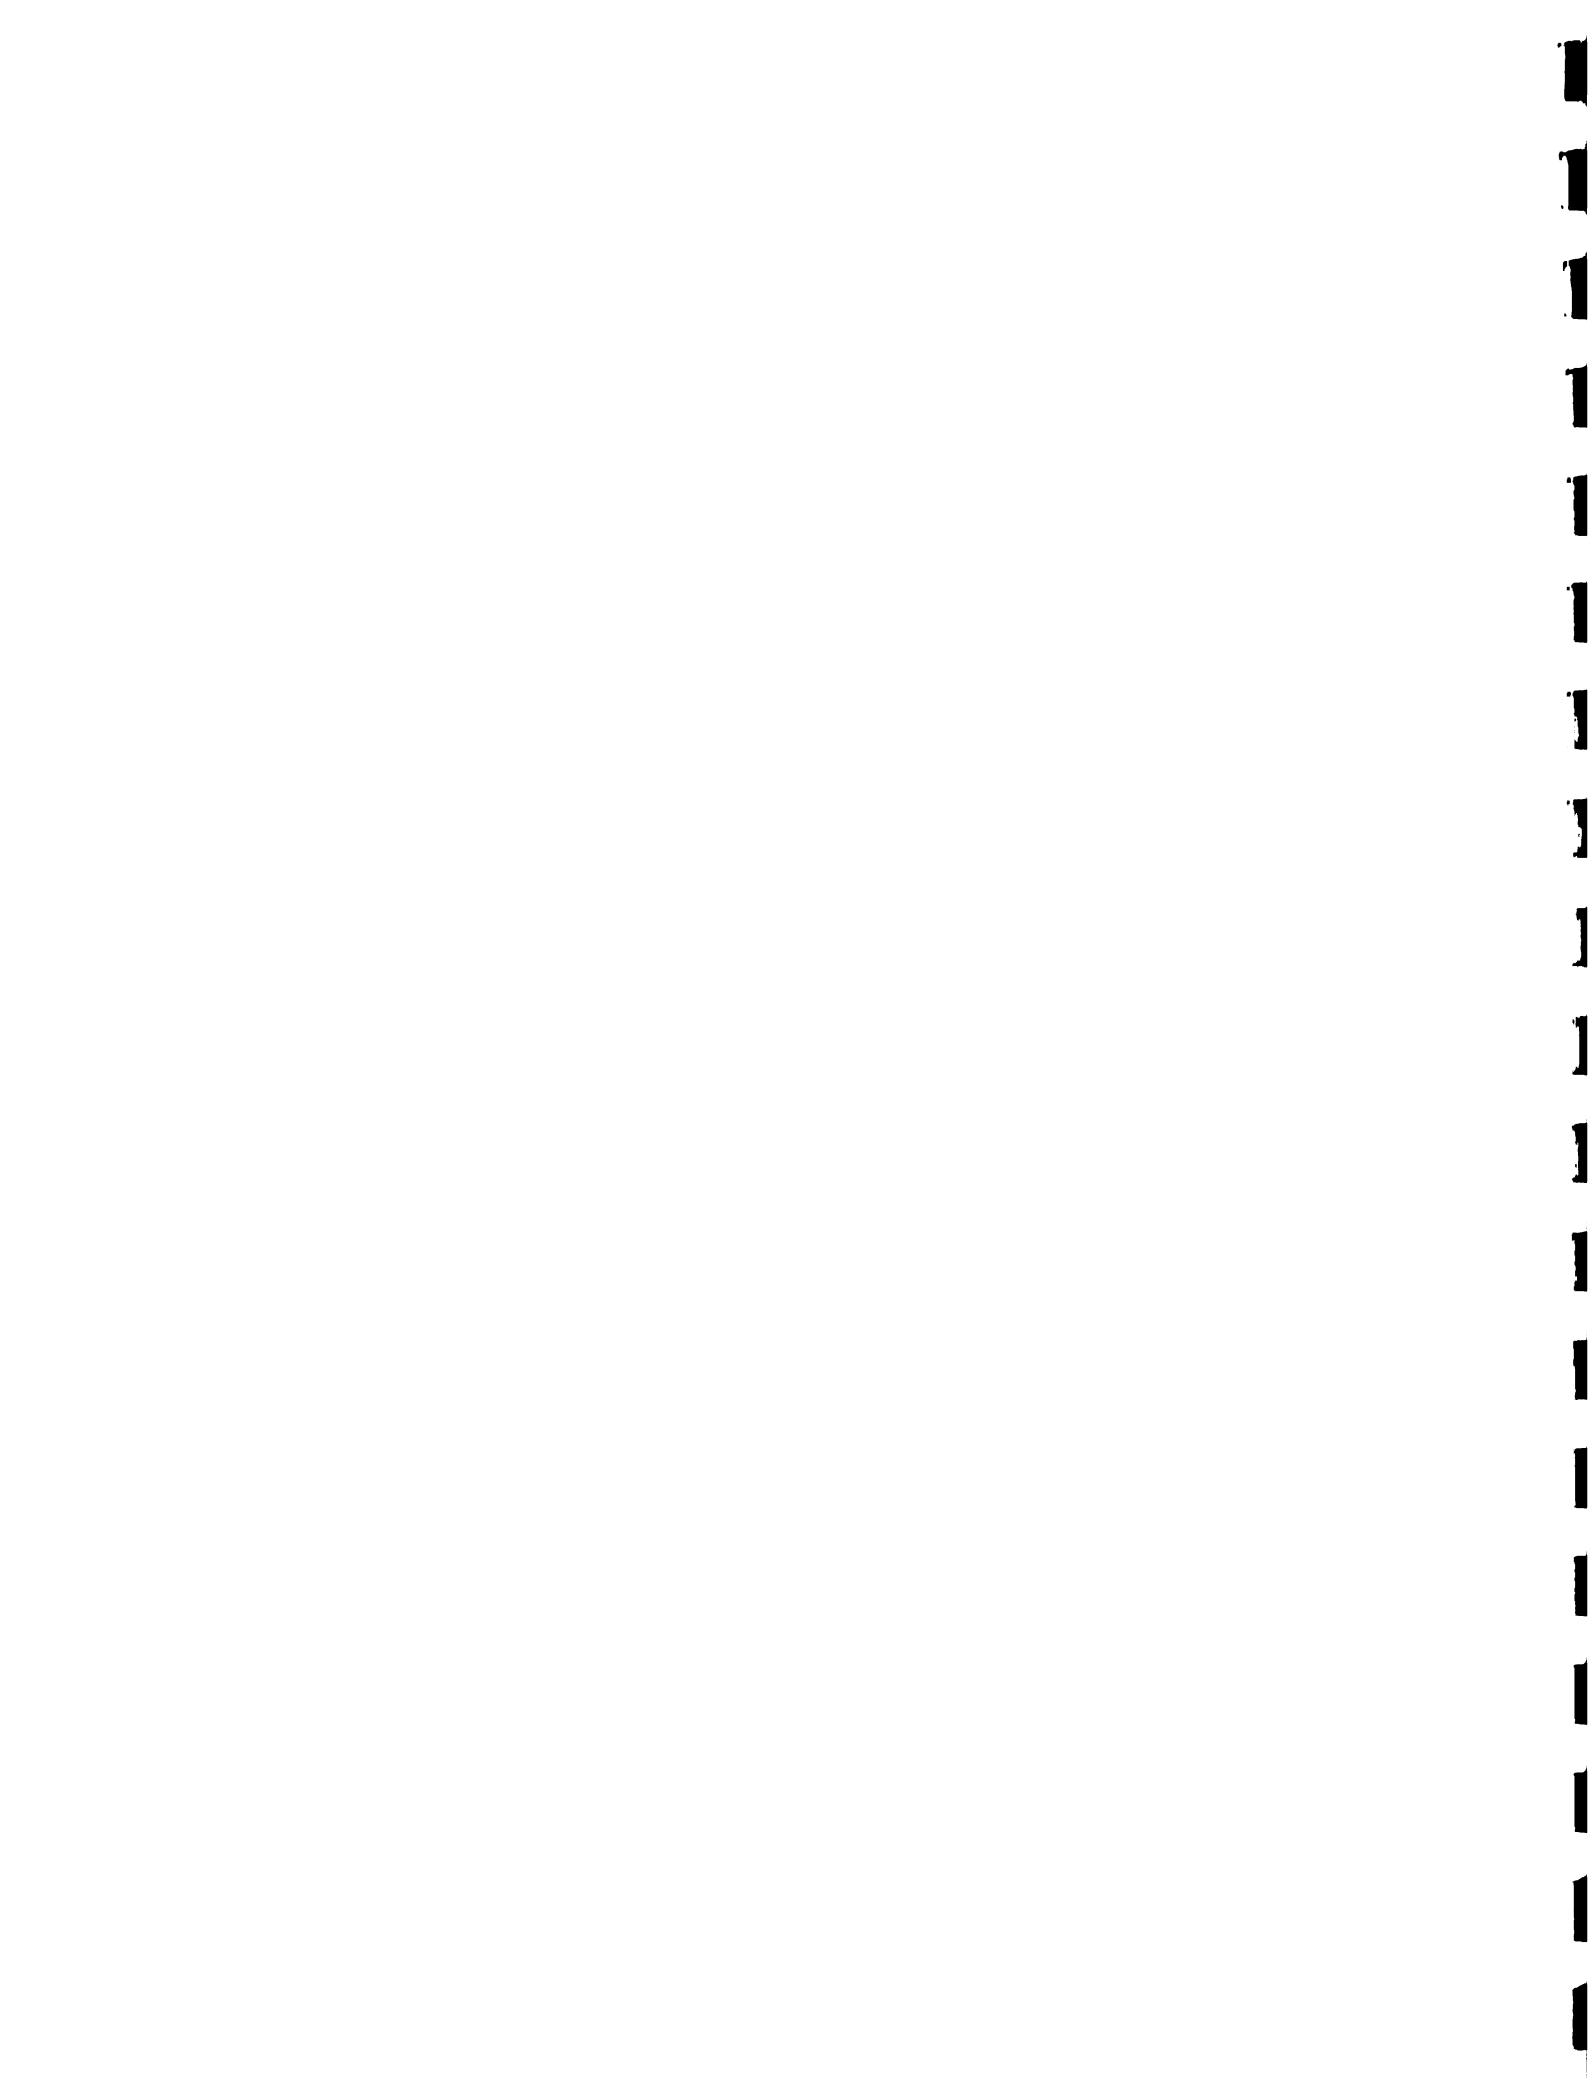

La temperatura registrada en Neyba aparece en el Cuadro 5. El promedio anual es de 26.8 °C. Si se asume un gradiente promedio de 0.6 °C/100 m, el promedio de la temperatura media anual para la altitud media de la cuenca (845.5 MSNM) resulta en 22.3 °C

3. Precipitación.

La definición de la precipitación sobre el área de la cuenca fue una de las tareas más importantes, considerando que estaba previsto el uso de un modelo lluviaescorrentía para reconstruir la serie de caudales en el sitio de El Millo, y que no se disponía de registros de lluvia dentro del área de la cuenca.

El primer paso fue colectar la información de lluvia en la región del Proyecto, para realizar la extrapolación a la cuenca del río Majagual.

Luego se seleccionaron las estaciones Los Guineos, Los Bolos, Guayabal y Neyba por ser las más cercanas a la cuenca, para analizar parcialmente la correlación entre sus registros, lo que permitiría completar datos faltantes en dichas estaciones y obtener una visión general del patrón de lluvia predominante.

En cinco de las estaciones más remotas con respecto al área de la cuenca no se completaron datos faltantes y el promedio anual se obtuvo a partir de la información disponible ..

Usando los procedimientos indicados se definieron las series de totales mensuales de precipitación de todas las estaciones para el período 1972-1984, que corresponde con la longitud de registro de los Bolos, el cual - fue usado para la generación de caudales con las correcciones que se discuten más adelante. Esta información se incluye como Anexo 1.

La estación de lluvia más cercana a la cuenca del río - Majagual hasta El Millo es la de Los Guineos, por lo que inicialmente se trató de utilizar los datos de ésta para estimar la lluvia sobre la cuenca. Sin embargo, la poca extensión del registro, la alta frecuencia con que se presentaban meses sin datos junto con la baja correlación lineal de sus totales mensuales para los meses húmedos con los correspondientes a las estaciones circundantes obligaron a usar el - registro de Los Bolos. La comparación de los aspectos generales de las estaciones de Los Guineos y Los Bolos permitió establecer lo siguiente:

-Ambas están ubicadas en la vertiente sur de la Sierra de Neyba, Los Guineos unos 11.0 Kms. al Noroeste del

Los resultados de los análisis de correlación lineal de las lluvias mensuales de las estaciones enumeradas y otras del área se muestran en el Cuadro 6.

Los totales mensuales faltantes en las demás estaciones cercanas a la cuenca en estudio fueron estimados por una relación proporcional entre el dato faltante y el total del año a que corresponde y los correspondientes de largo plazo para la misma estación:

$$\frac{X_i}{N_i} = \frac{\Sigma X_c + \Sigma X_d}{P} \quad , \text{ donde}$$

X_i = dato a estimar para el mes i.

N_i = precipitación media mensual de largo plazo para el mes i.

ΣX_c = sumatoria de los totales mensuales conocidos en el año de X_i .

ΣX_d = sumatoria de los totales mensuales desconocidos en el año de X_i : (incluye a X_i).

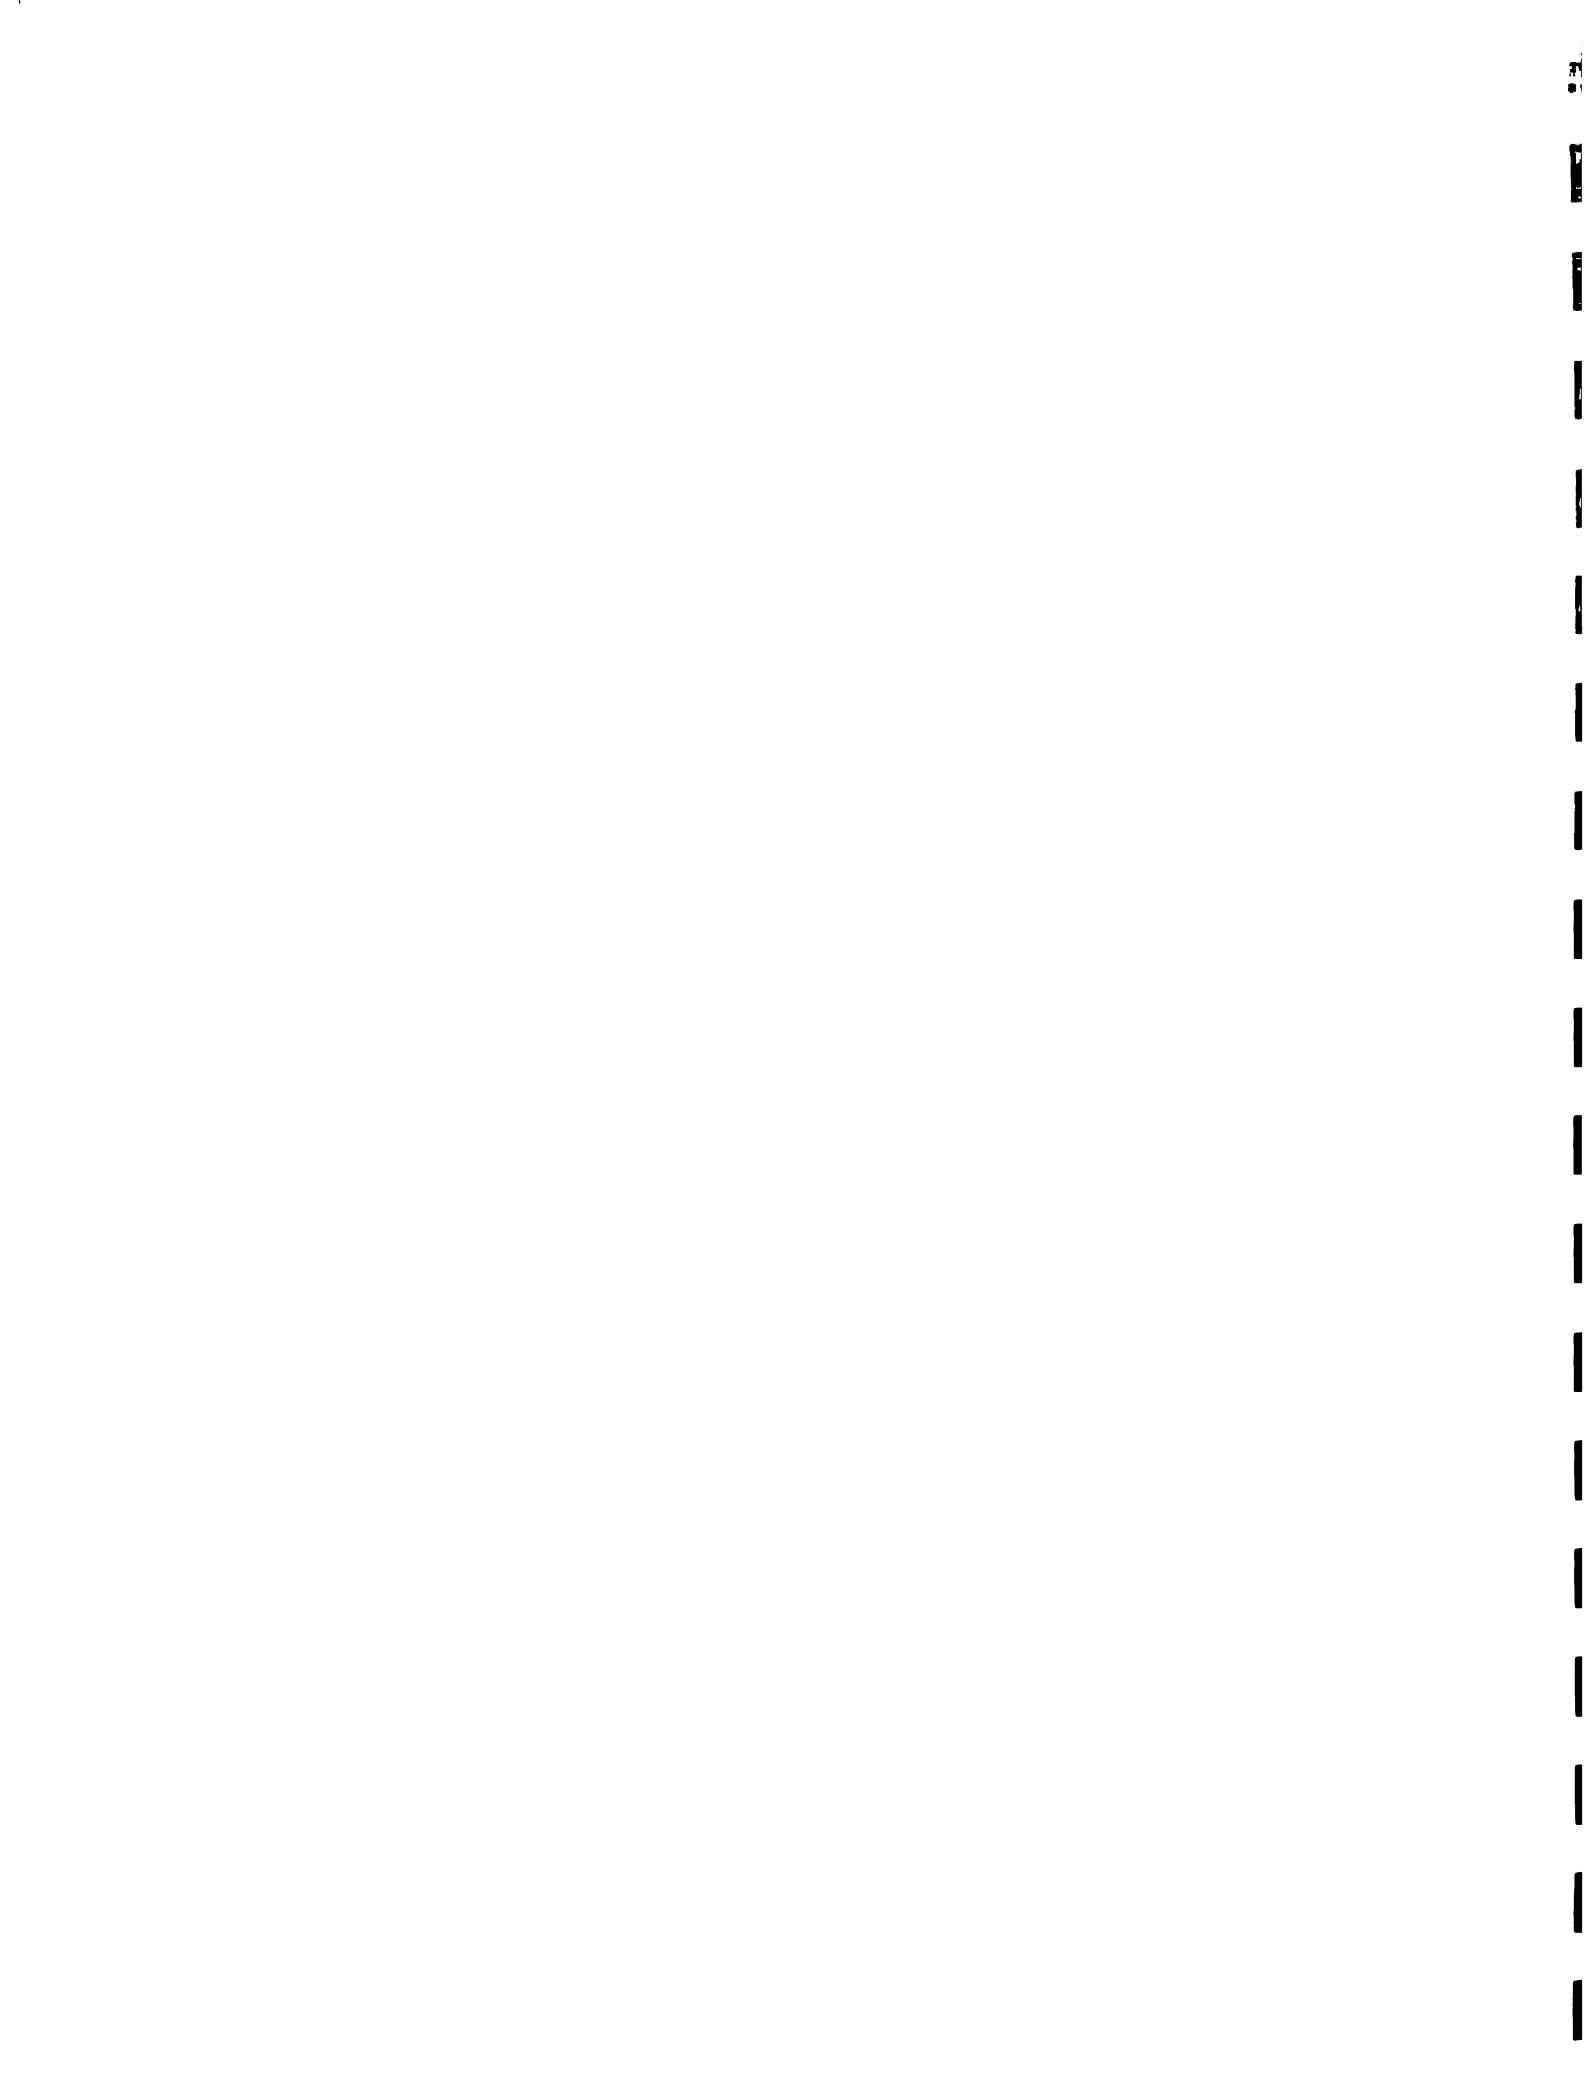

P = precipitación media anual de largo plazo.

centro de la cuenca, y Los Bolos a unos 34.0 Kms. también al Noroeste.

-La altitud en Los Guineos es de 700 MSNM y Los Bolos 1200 MSNM, mientras que la altitud media de la cuenca es de 845.5 MSNM.

-La precipitación anual evaluada en cada estación a partir de los totales mensuales para el período común de datos es muy similar, con 1684.2 mm en Los Guineos y 1681.8 mm en Los Bolos.

Por otra parte, la distribución mensual de la precipitación media anual, que aparece en la Figura 3, muestra un régimen pluviométrico más uniforme en Los Bolos que en Los Guineos, posiblemente por la localización de éste último sitio con respecto al flujo de vientos del noreste que entran por el Valle de San Juan. Esta condición podría explicar la similitud de la lluvia anual, aunque la divisoria en los alrededores de Los Bolos es más alta que la correspondiente a Los Guineos.

Usando la información antes mencionada se trazaron las isoyetas anuales para el período 1972-1984, del Mapa No.2.

Obtenida la lluvia media sobre el área de la cuenca hasta El Millo, se calculó el valor para corregir la lluvia de Los Bolos, $K_1 = 0.889$, mediante

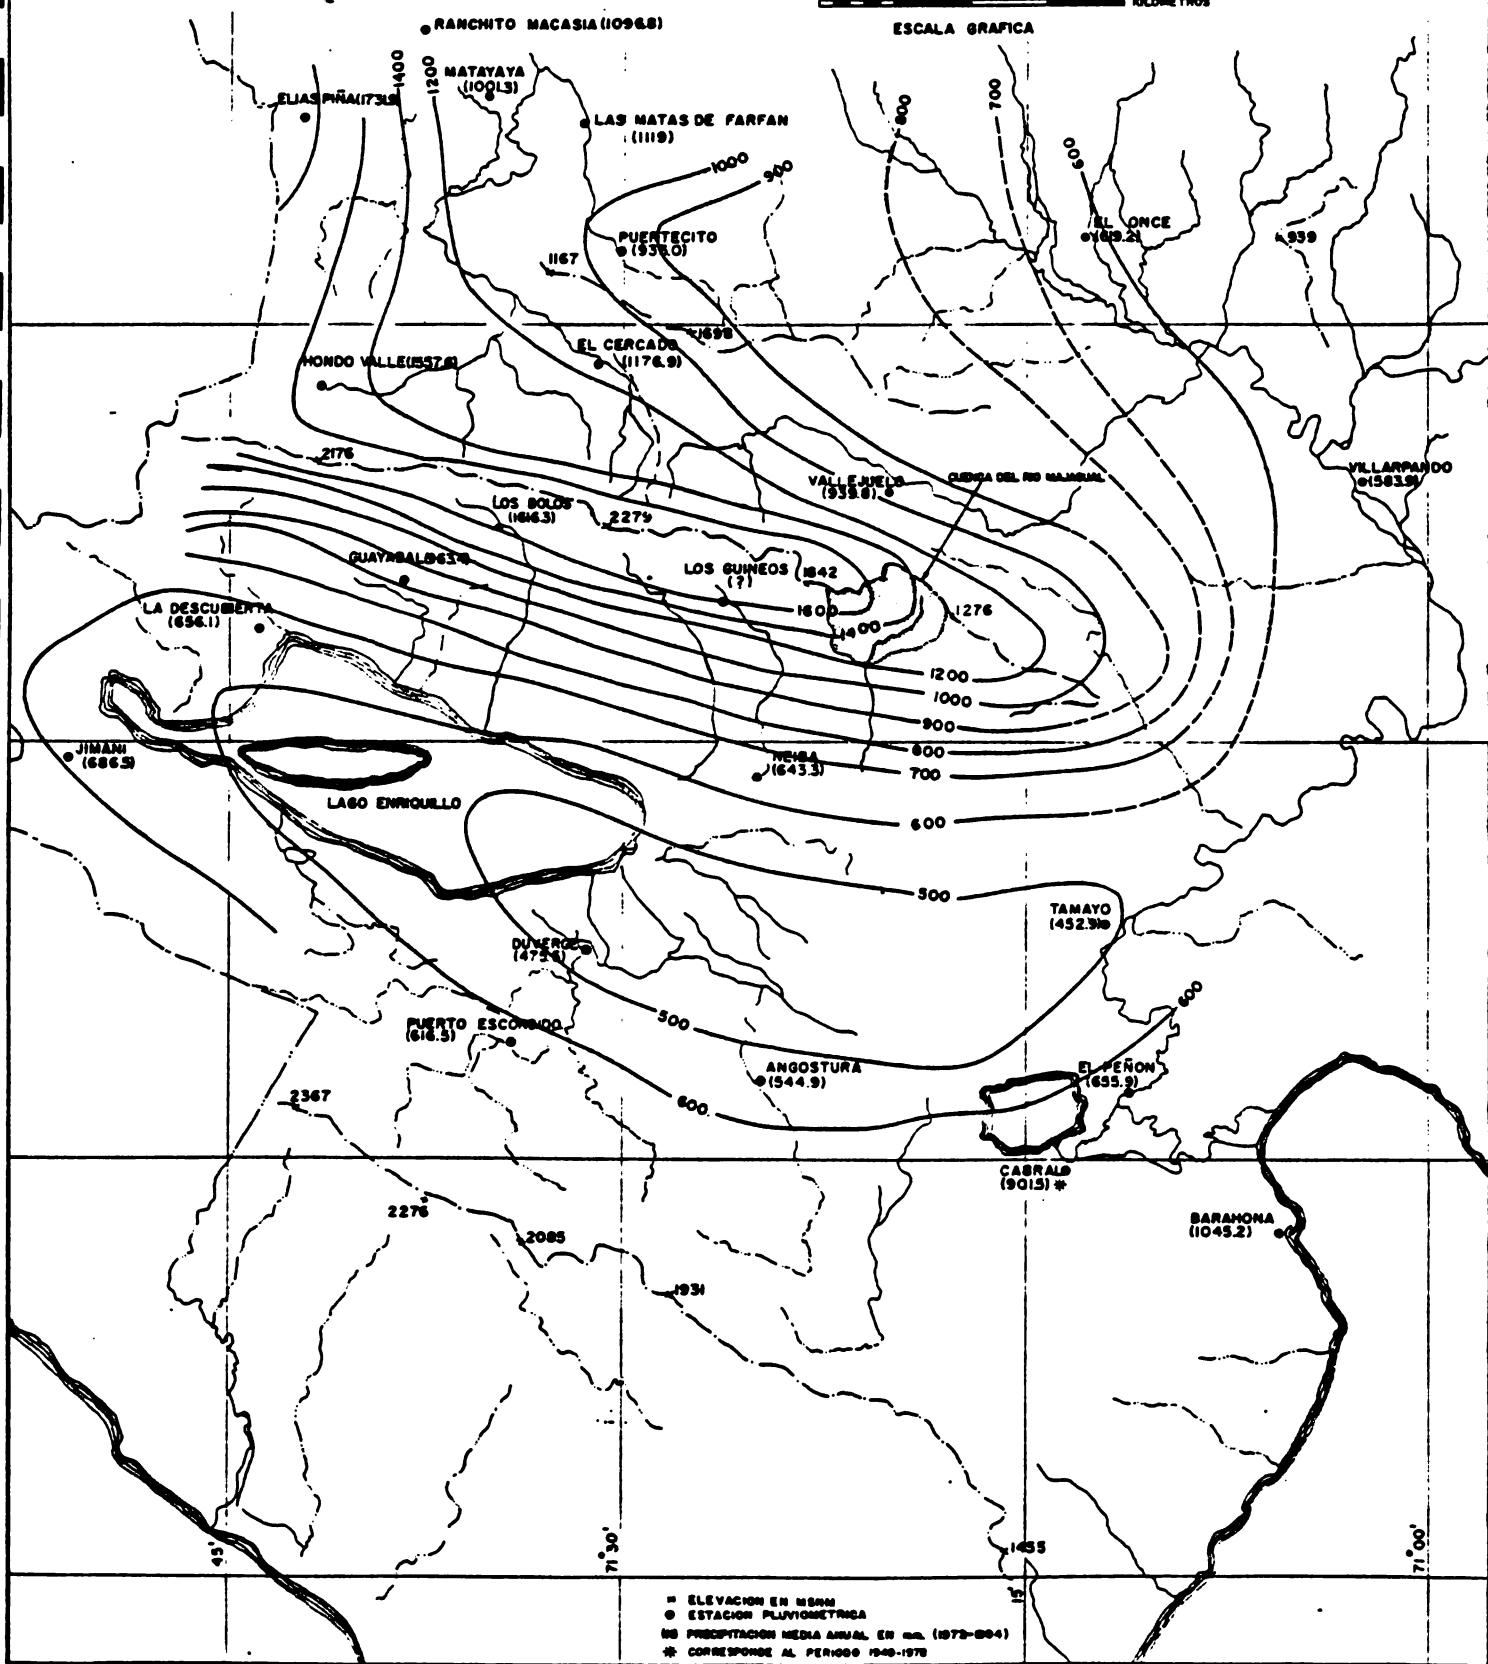

$$K_1 = \frac{\text{Pareal}}{\text{PL Bolos}}, \text{ donde}$$

MAPA N° 2

ISOETAS MEDIAS ANUALES PERÍODO 1972-1984.

8 9 10 11 EN-0285 TR02

ESCALA GRAFICA

K₁ = Coeficiente que corrige la lluvia de Los Bolos

Pareal= Precipitación sobre el área de la cuenca

PL Bolos= Precipitación en Los Bolos.

Al inicio de los estudios se instalaron sendos pluviómetros en Neyba y El Majagual, este último en la cuenca - del río del mismo nombre.

4. Circulación Atmosférica.

El patrón local de circulación atmosférica en el área de la cuenca parece estar regido por tres flujos de vientos - principales:

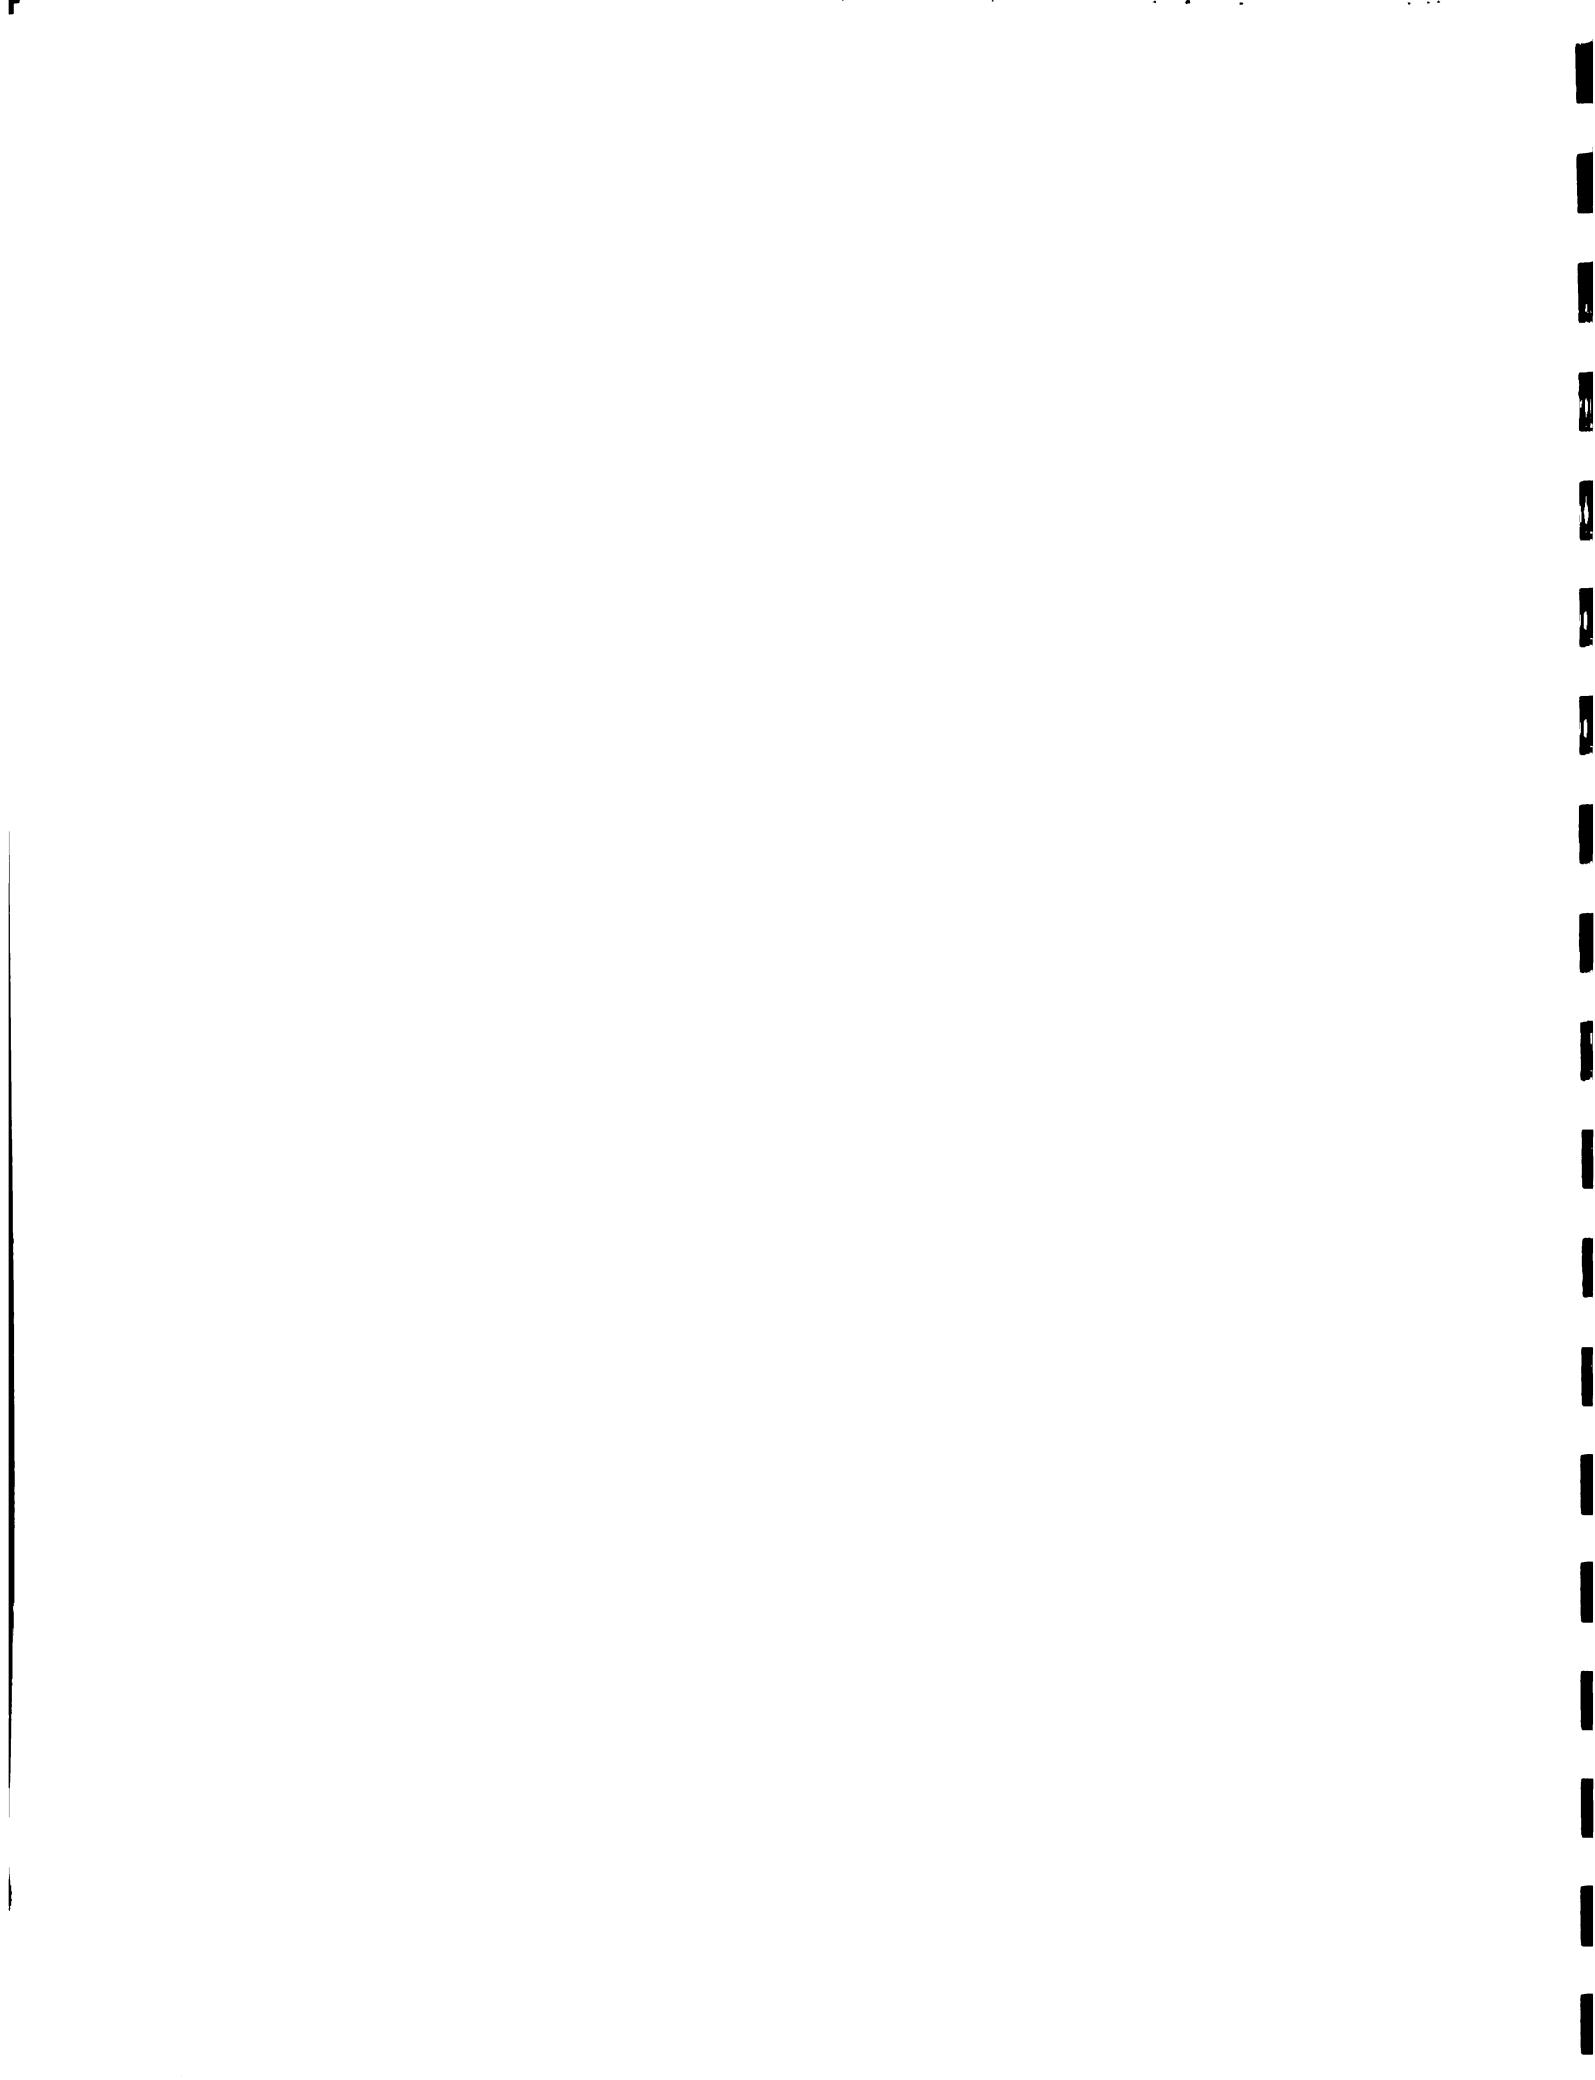

i) El flujo húmedo con dirección SE que penetra a tierra a través de la Bahía de Neyba y que cruza sobre el Valle del mismo nombre hasta alcanzar la Sierra.

ii) La circulación desde el Lago Enriquillo con sus variaciones diurnas- nocturnas

iii) El flujo que entra por NE a través del Valle del río San Juan.

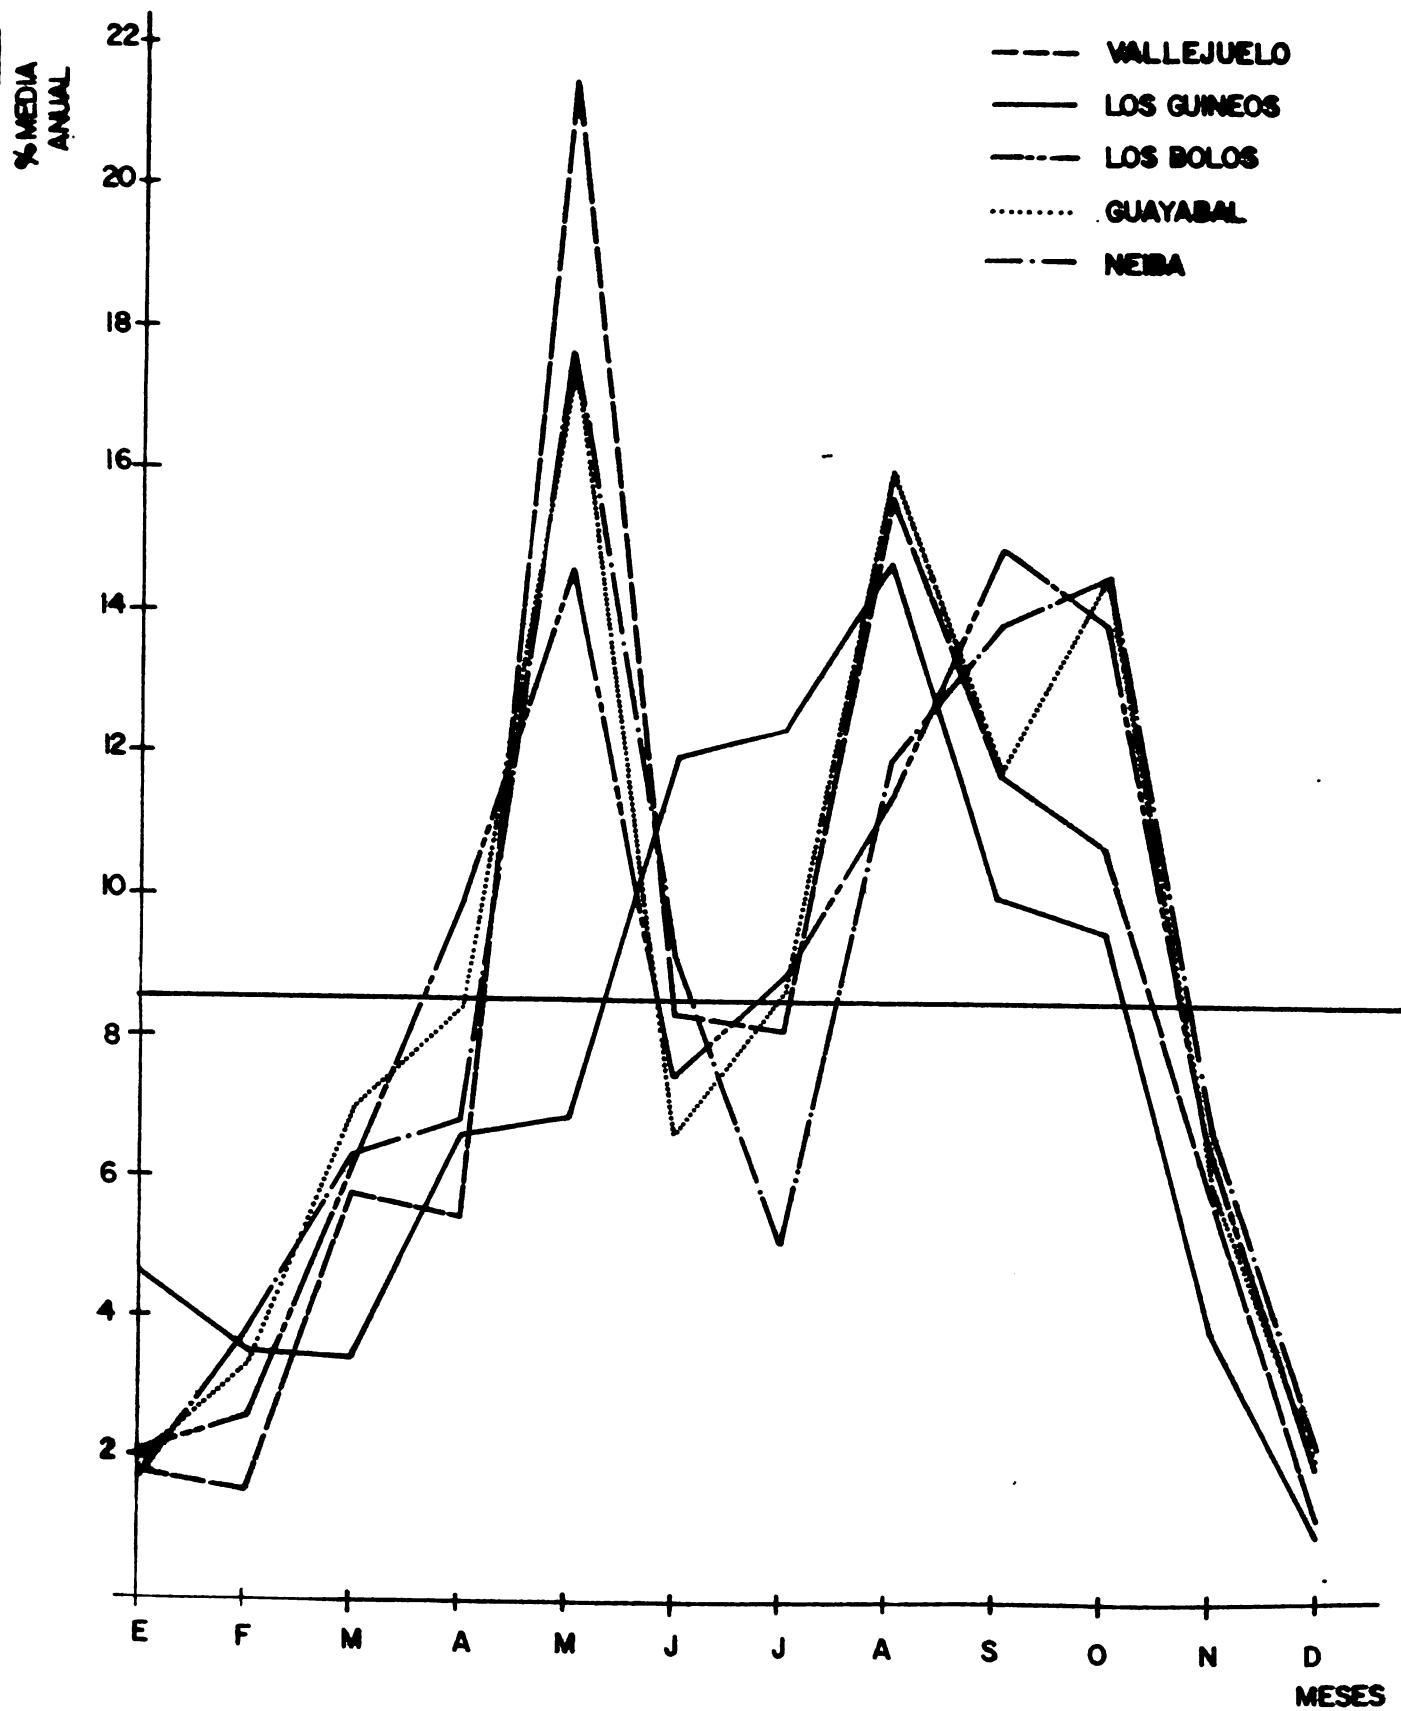

Durante los meses del estiaje principal (enero-marzo) el factor predominante parece ser el flujo desde el Lago; lo cual es corroborado por la alta correlación entre las lluvias mensuales.

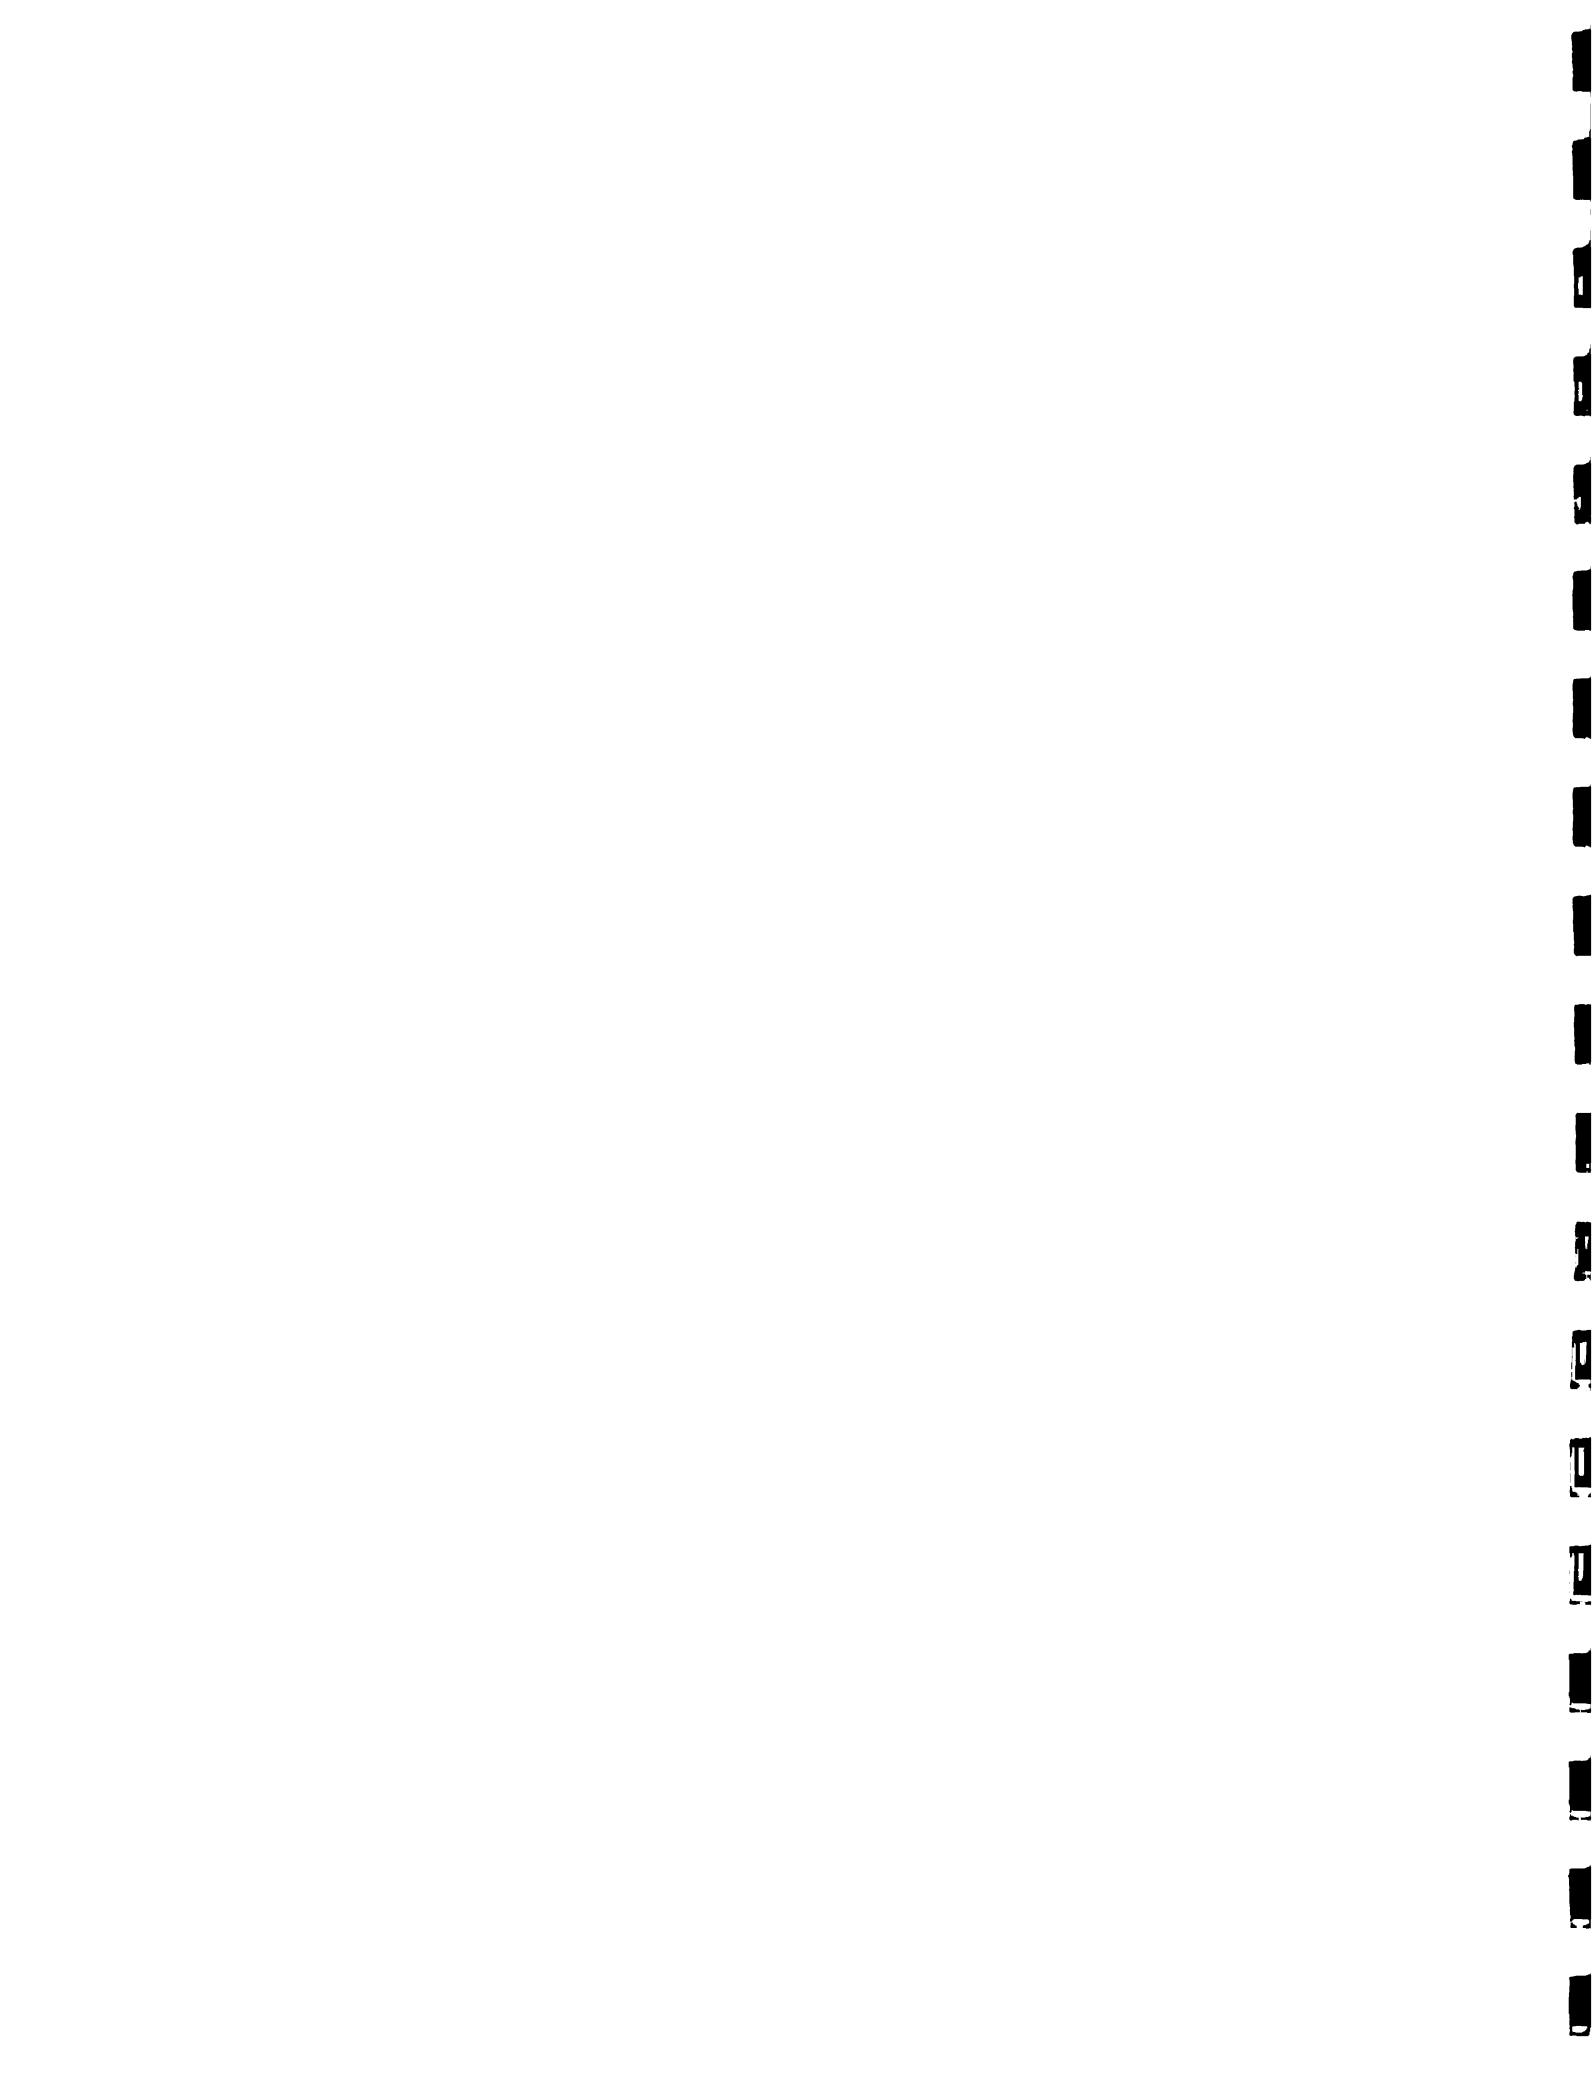

En el período de mayor pluviosidad (mayo-junio), parece haber predominio de la circulación NE proveniente del

DISTRIBUCION DE PORCENTAJES MENSUALES
DE LA PRECIPITACION MEDIA MENSUAL

-21-

Valle de San Juan y SE del mar a través de la Bahía de Neyba, lo cual podría explicar la sensible caída de la correlación lineal de los registros de lluvia, como se discutió en la sección. III.3.

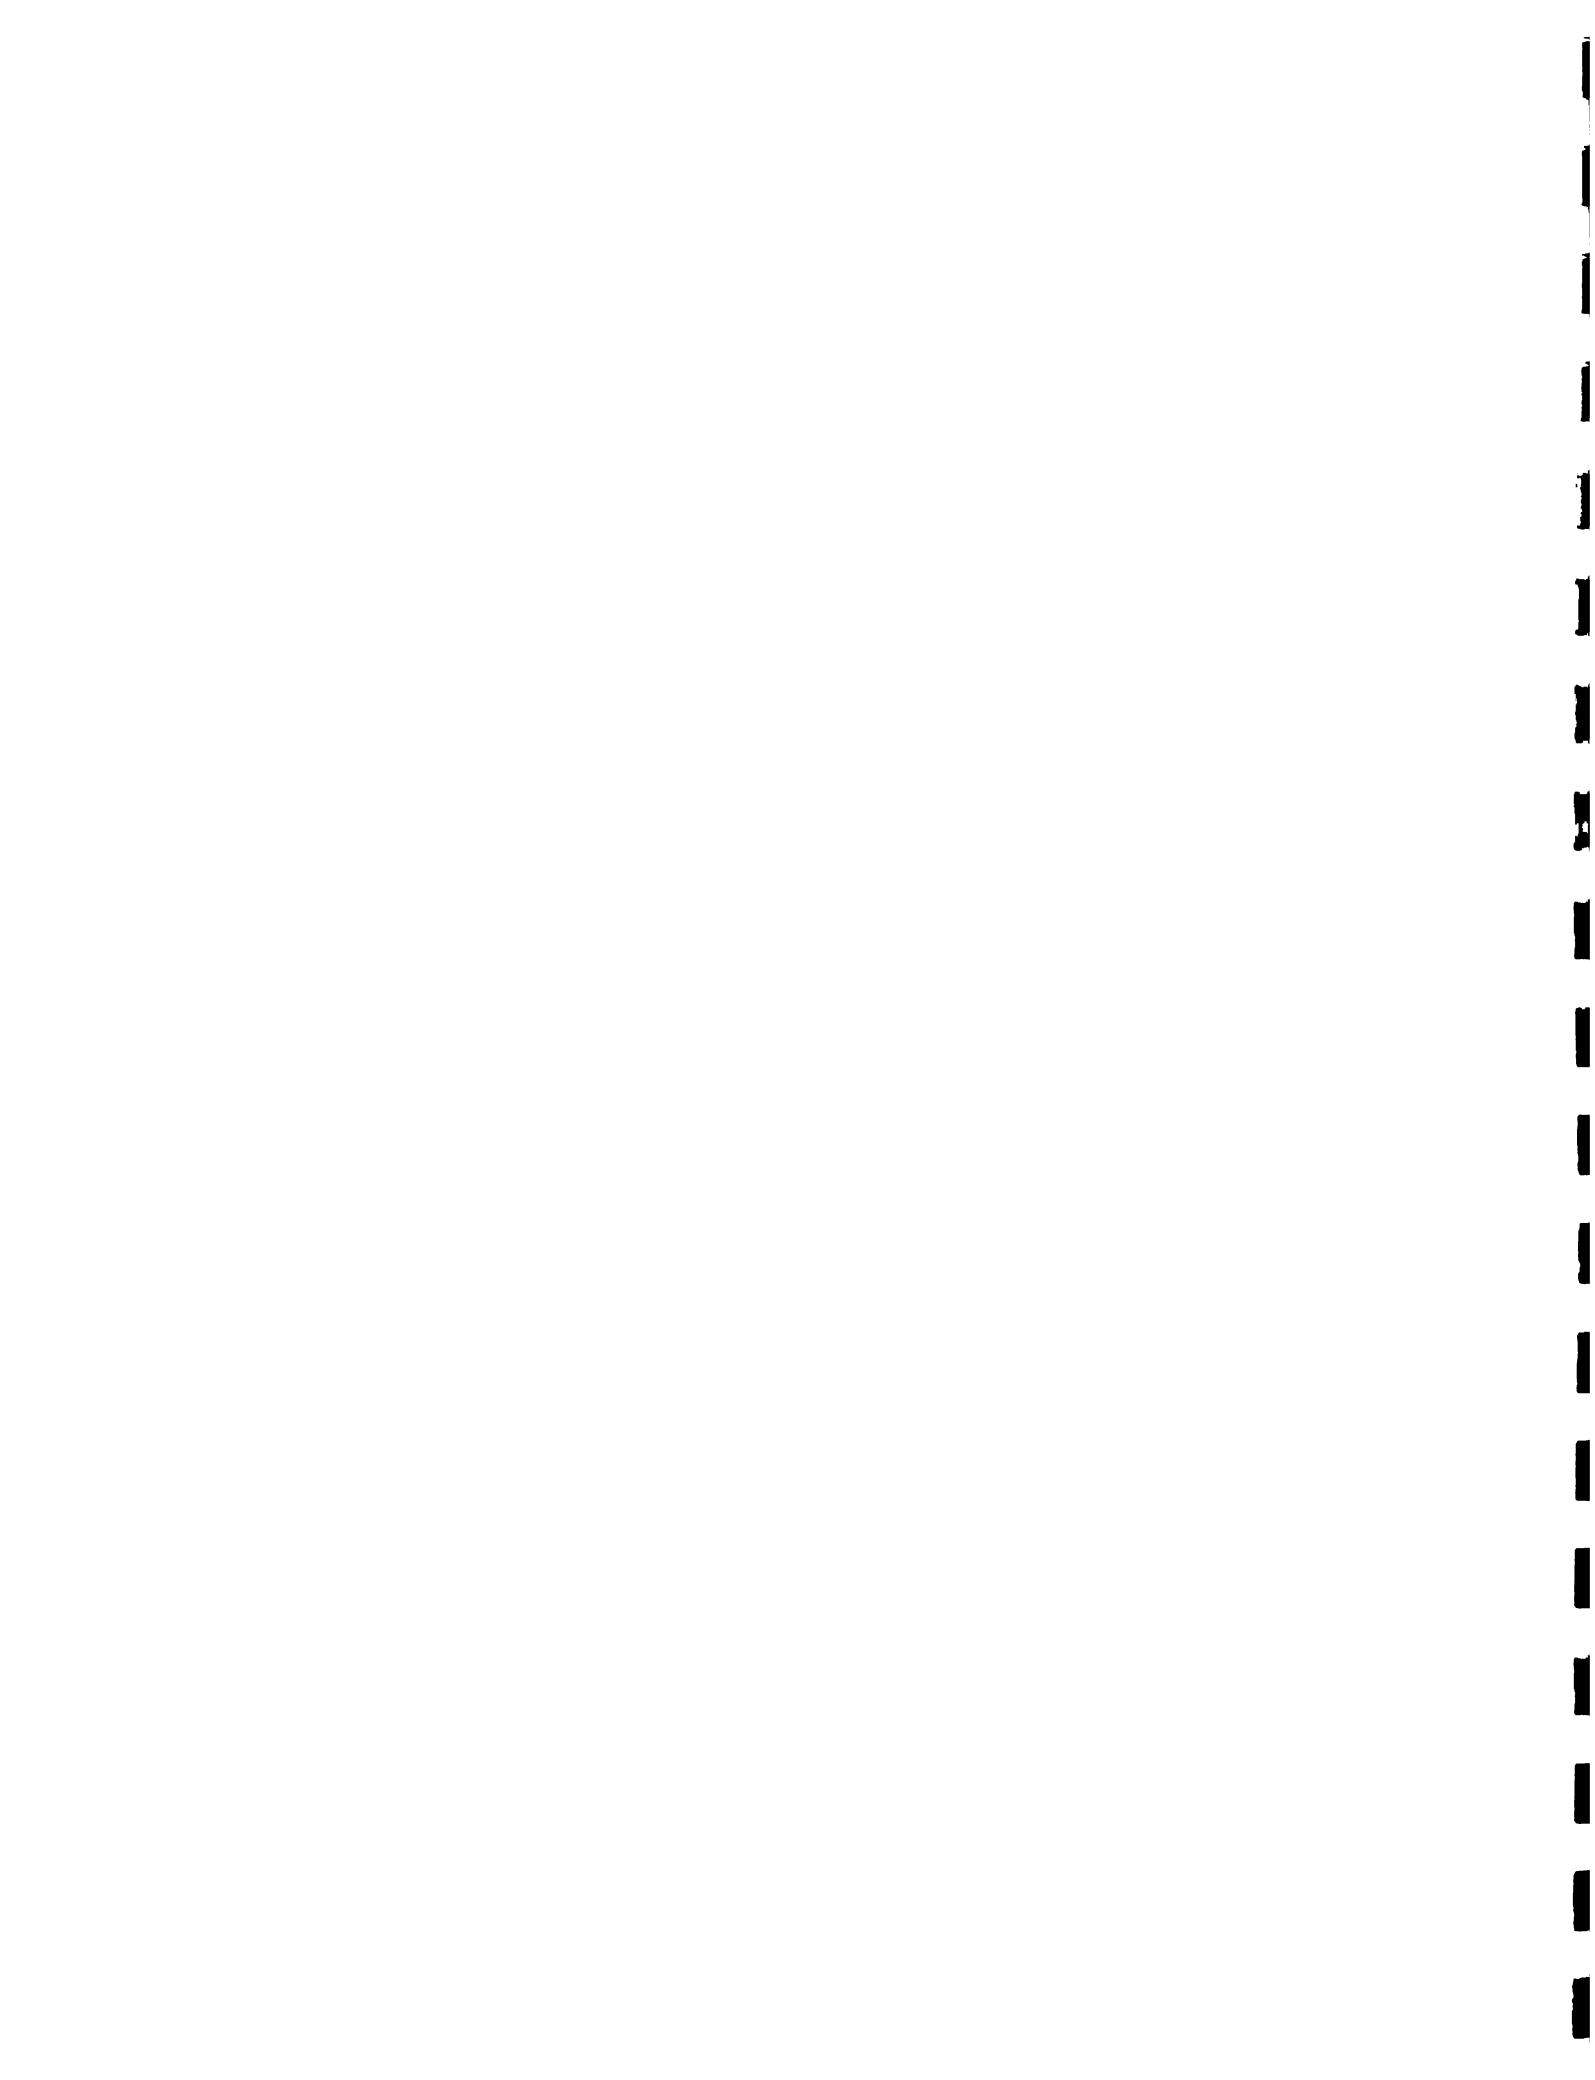

Durante los meses julio- septiembre, correspondiente al período de huracanes se presenta la erradicidad pluviométrica característica del predominio de los sistemas de alta y baja presión.

Estos supuestos a nivel local parecen encajar adecuadamente en el modelo descrito por Jorge (1970) para la isla de Santo Domingo y que explica la acción del frente tropical (TF) durante los meses de enero y febrero, provocando las lluvias máximas en la franja entre el Océano Atlántico y la Cordillera Septentrional y un predominio de la circulación local en el resto del país.

Durante abril y mayo el paso hacia el norte del sistema subtropical norte (STN) produce los valores máximos de precipitación sobre la isla, mientras que la acción del sistema de la ITC produce la erradicidad climática característica de los meses del período de huracanes (julio- agosto). Finalmente, en los meses octubre- noviembre se produce un segundo período - lluvioso provocado por el paso del STN hacia el sur.

5. Evaporación

El Cuadro 7 contiene los datos de evaporación registrados en la tina "A" de la estación de Neyba.

Nota: *Valores estimados con los datos de los días disponibles.

En aquellos meses en que faltaban datos para algunos días, se estimó el total mensual usando una proporción directa con la evaporación total de los días con datos.

La evaporación de agua en el área de la cuenca fue asumida como un 80 porciento de la correspondiente a Neyba, - para tomar en cuenta la mayor nubosidad asociada a la mayor pluviosidad, así como un probable valor más alto de la humedad relativa, inducido por la reducción de la temperatura con la altitud.

IV. MODELO LLUVIA-ESCORRENTIA.

En razón de que sólo se disponía de algunos aforos esporádicos en el sitio del río Majagual en El Milló y en los demás ríos que descienden de la Sierra de Neyba, se hizo indispensable el desarrollo de un modelo lluvia-escorrentía que permitiera la transformación a caudales de la lluvia estimada sobre la cuenca.

El modelo utilizado es una versión simplificada del Stanford Watershed Model IV, descrito por Crawford y Linsley (1966). El modelo procesa la información a intervalo diario, siendo sus entradas los parámetros que describen las características de la cuenca, la lluvia diaria y la evapotranspiración potencial total mensual. Opcionalmente se pueden suministrar los caudales medios mensuales observados a la salida de la cuenca, para fines de comparación con los caudales simulados por el modelo. Los resultados suministrados son el caudal diario - simulado, la evapotranspiración real mensual y las láminas almacenadas al final de cada mes.

En la Figura 4 se muestra el diagrama de flujo modelo y en el Anexo 2 se hace una descripción de las funciones del mismo.

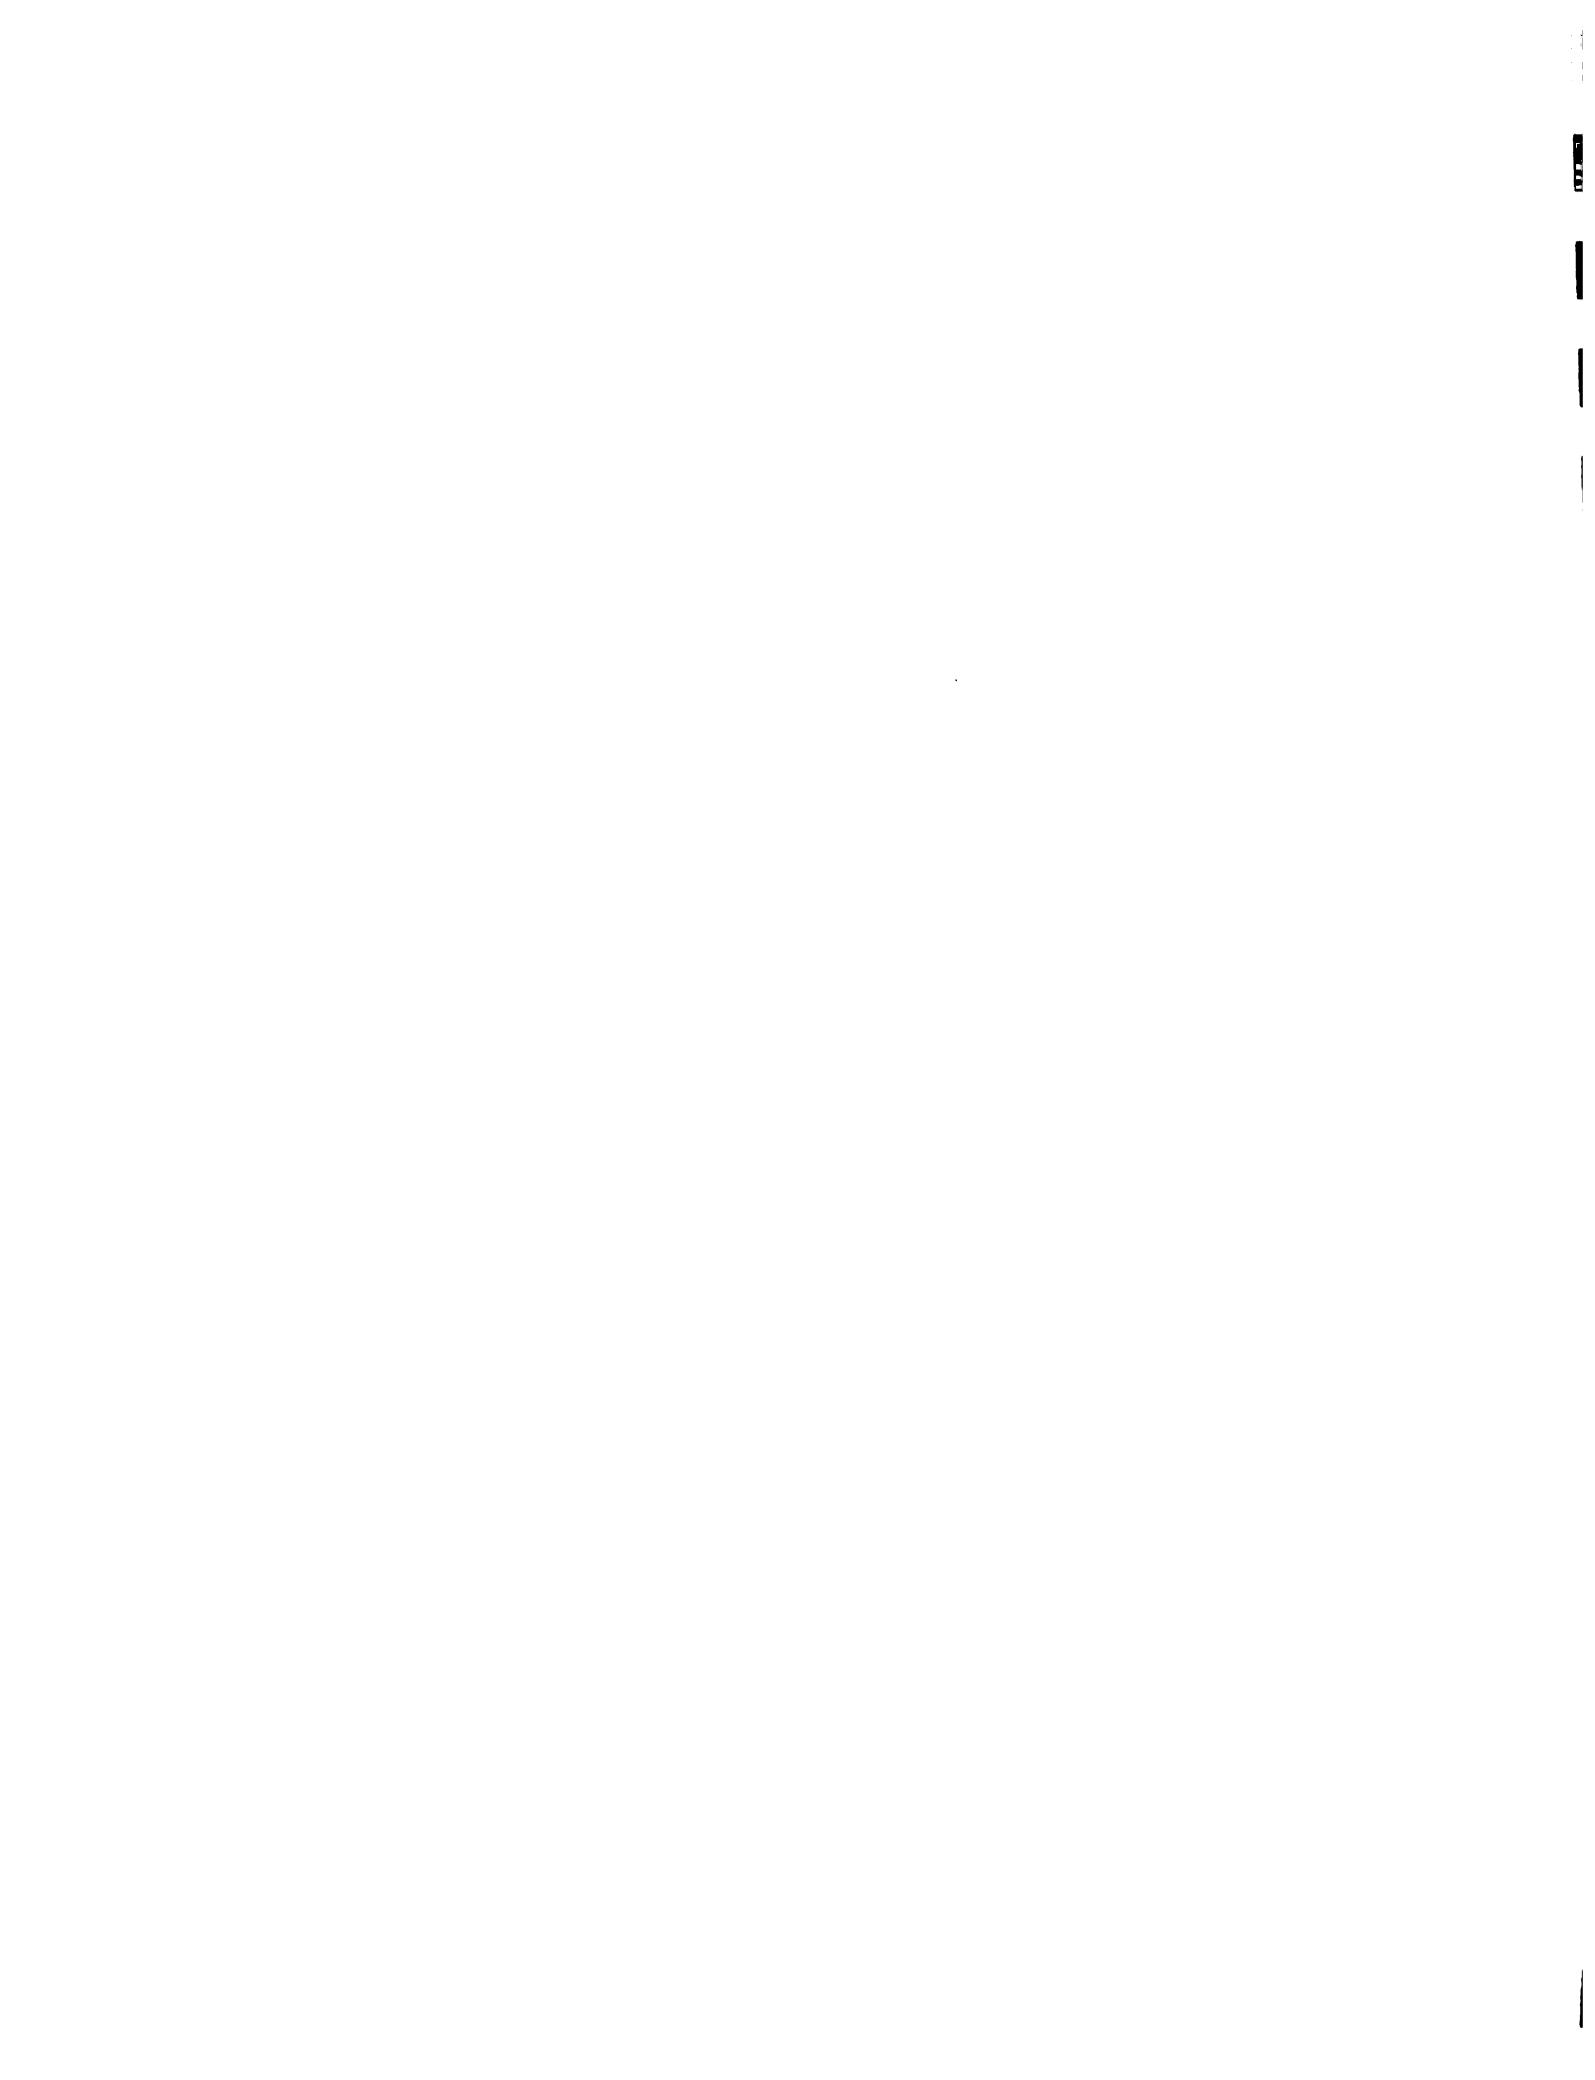

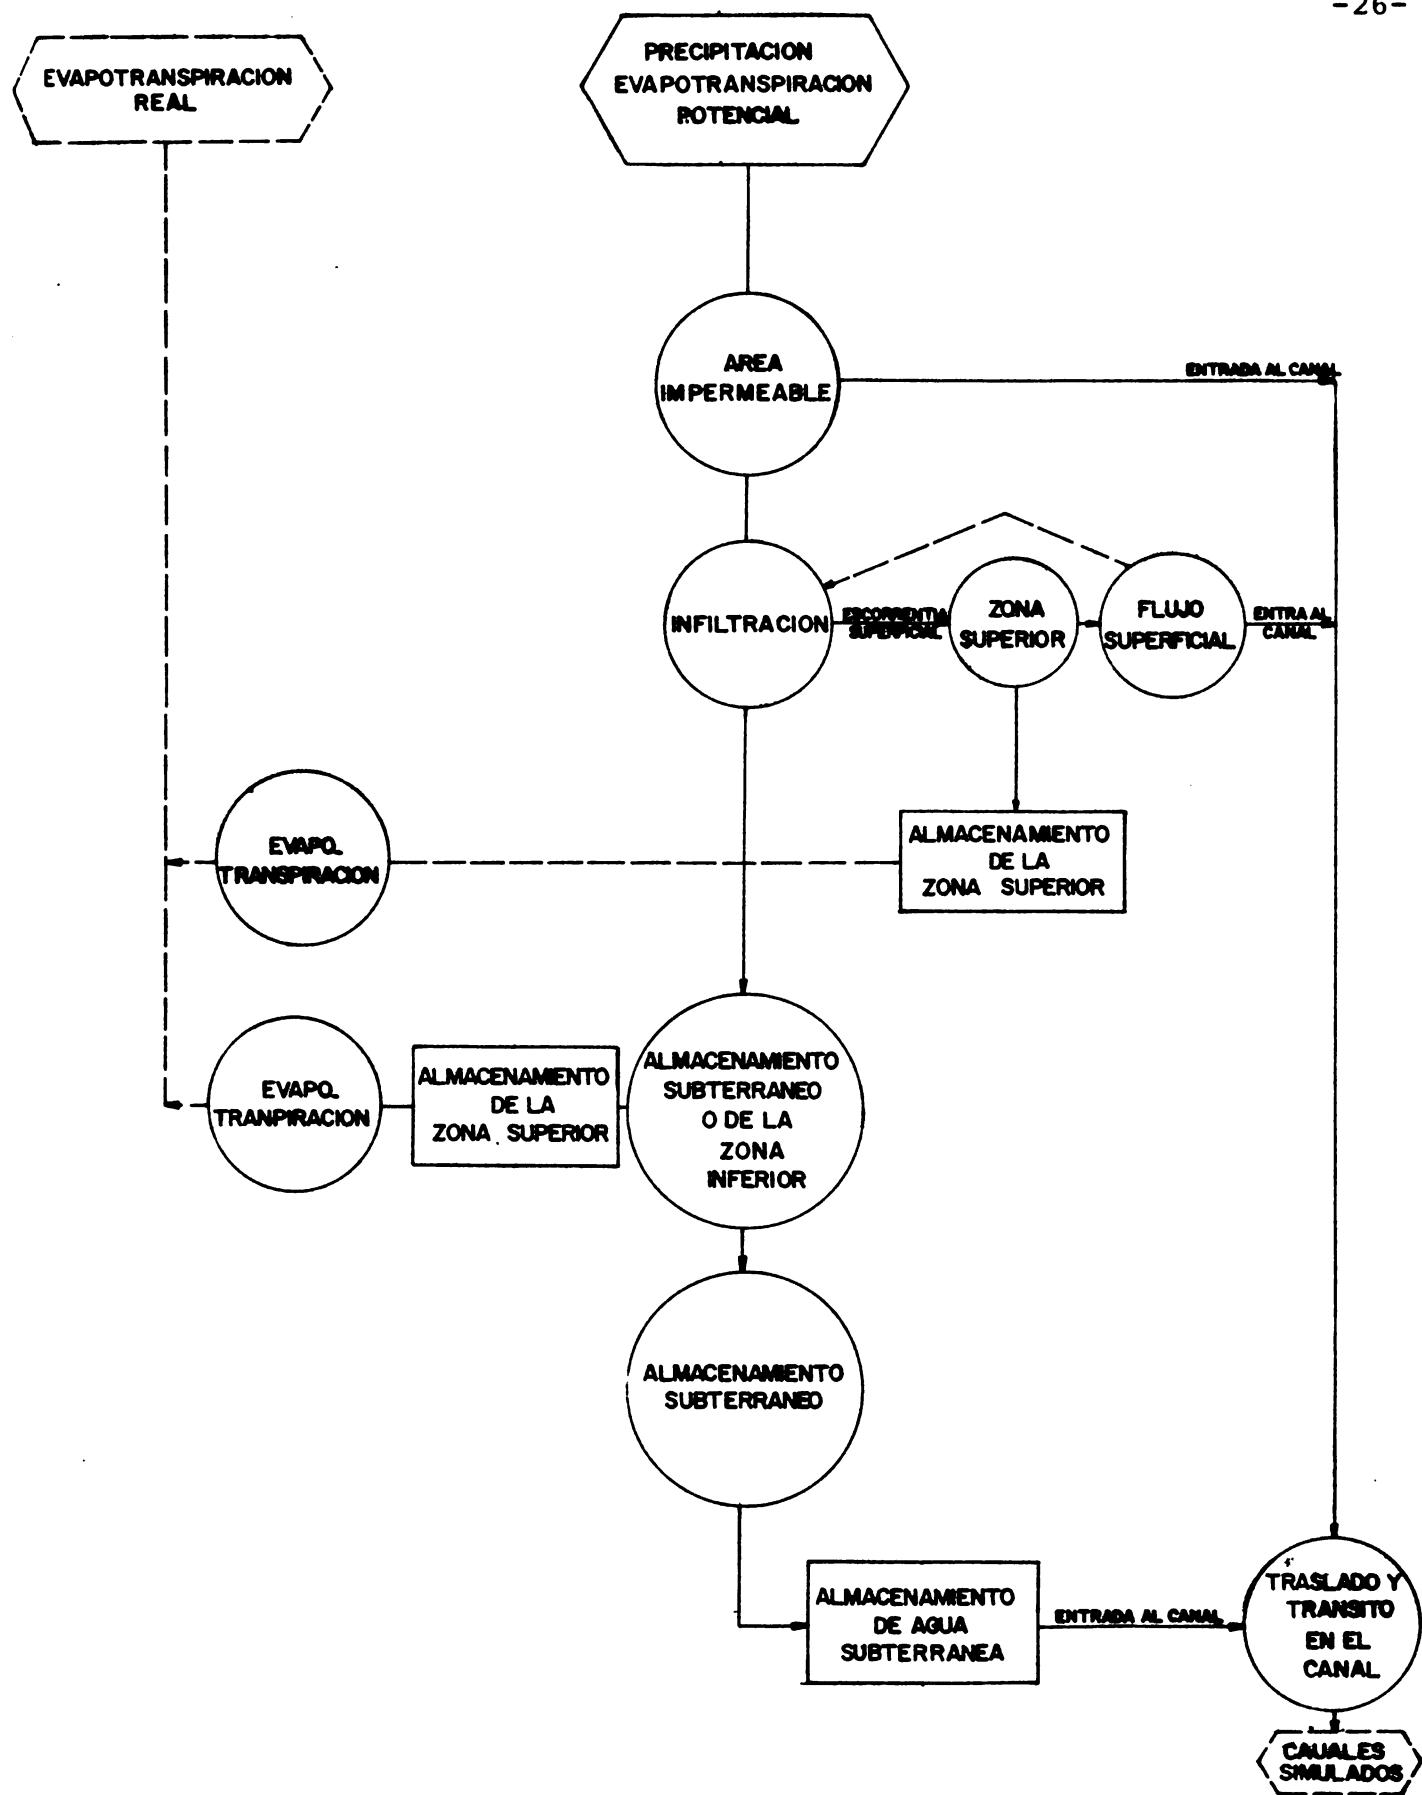

DIAGRAMA DE FLUJO DEL MODELO LLUVIA-ESCORRENTIA

-26-

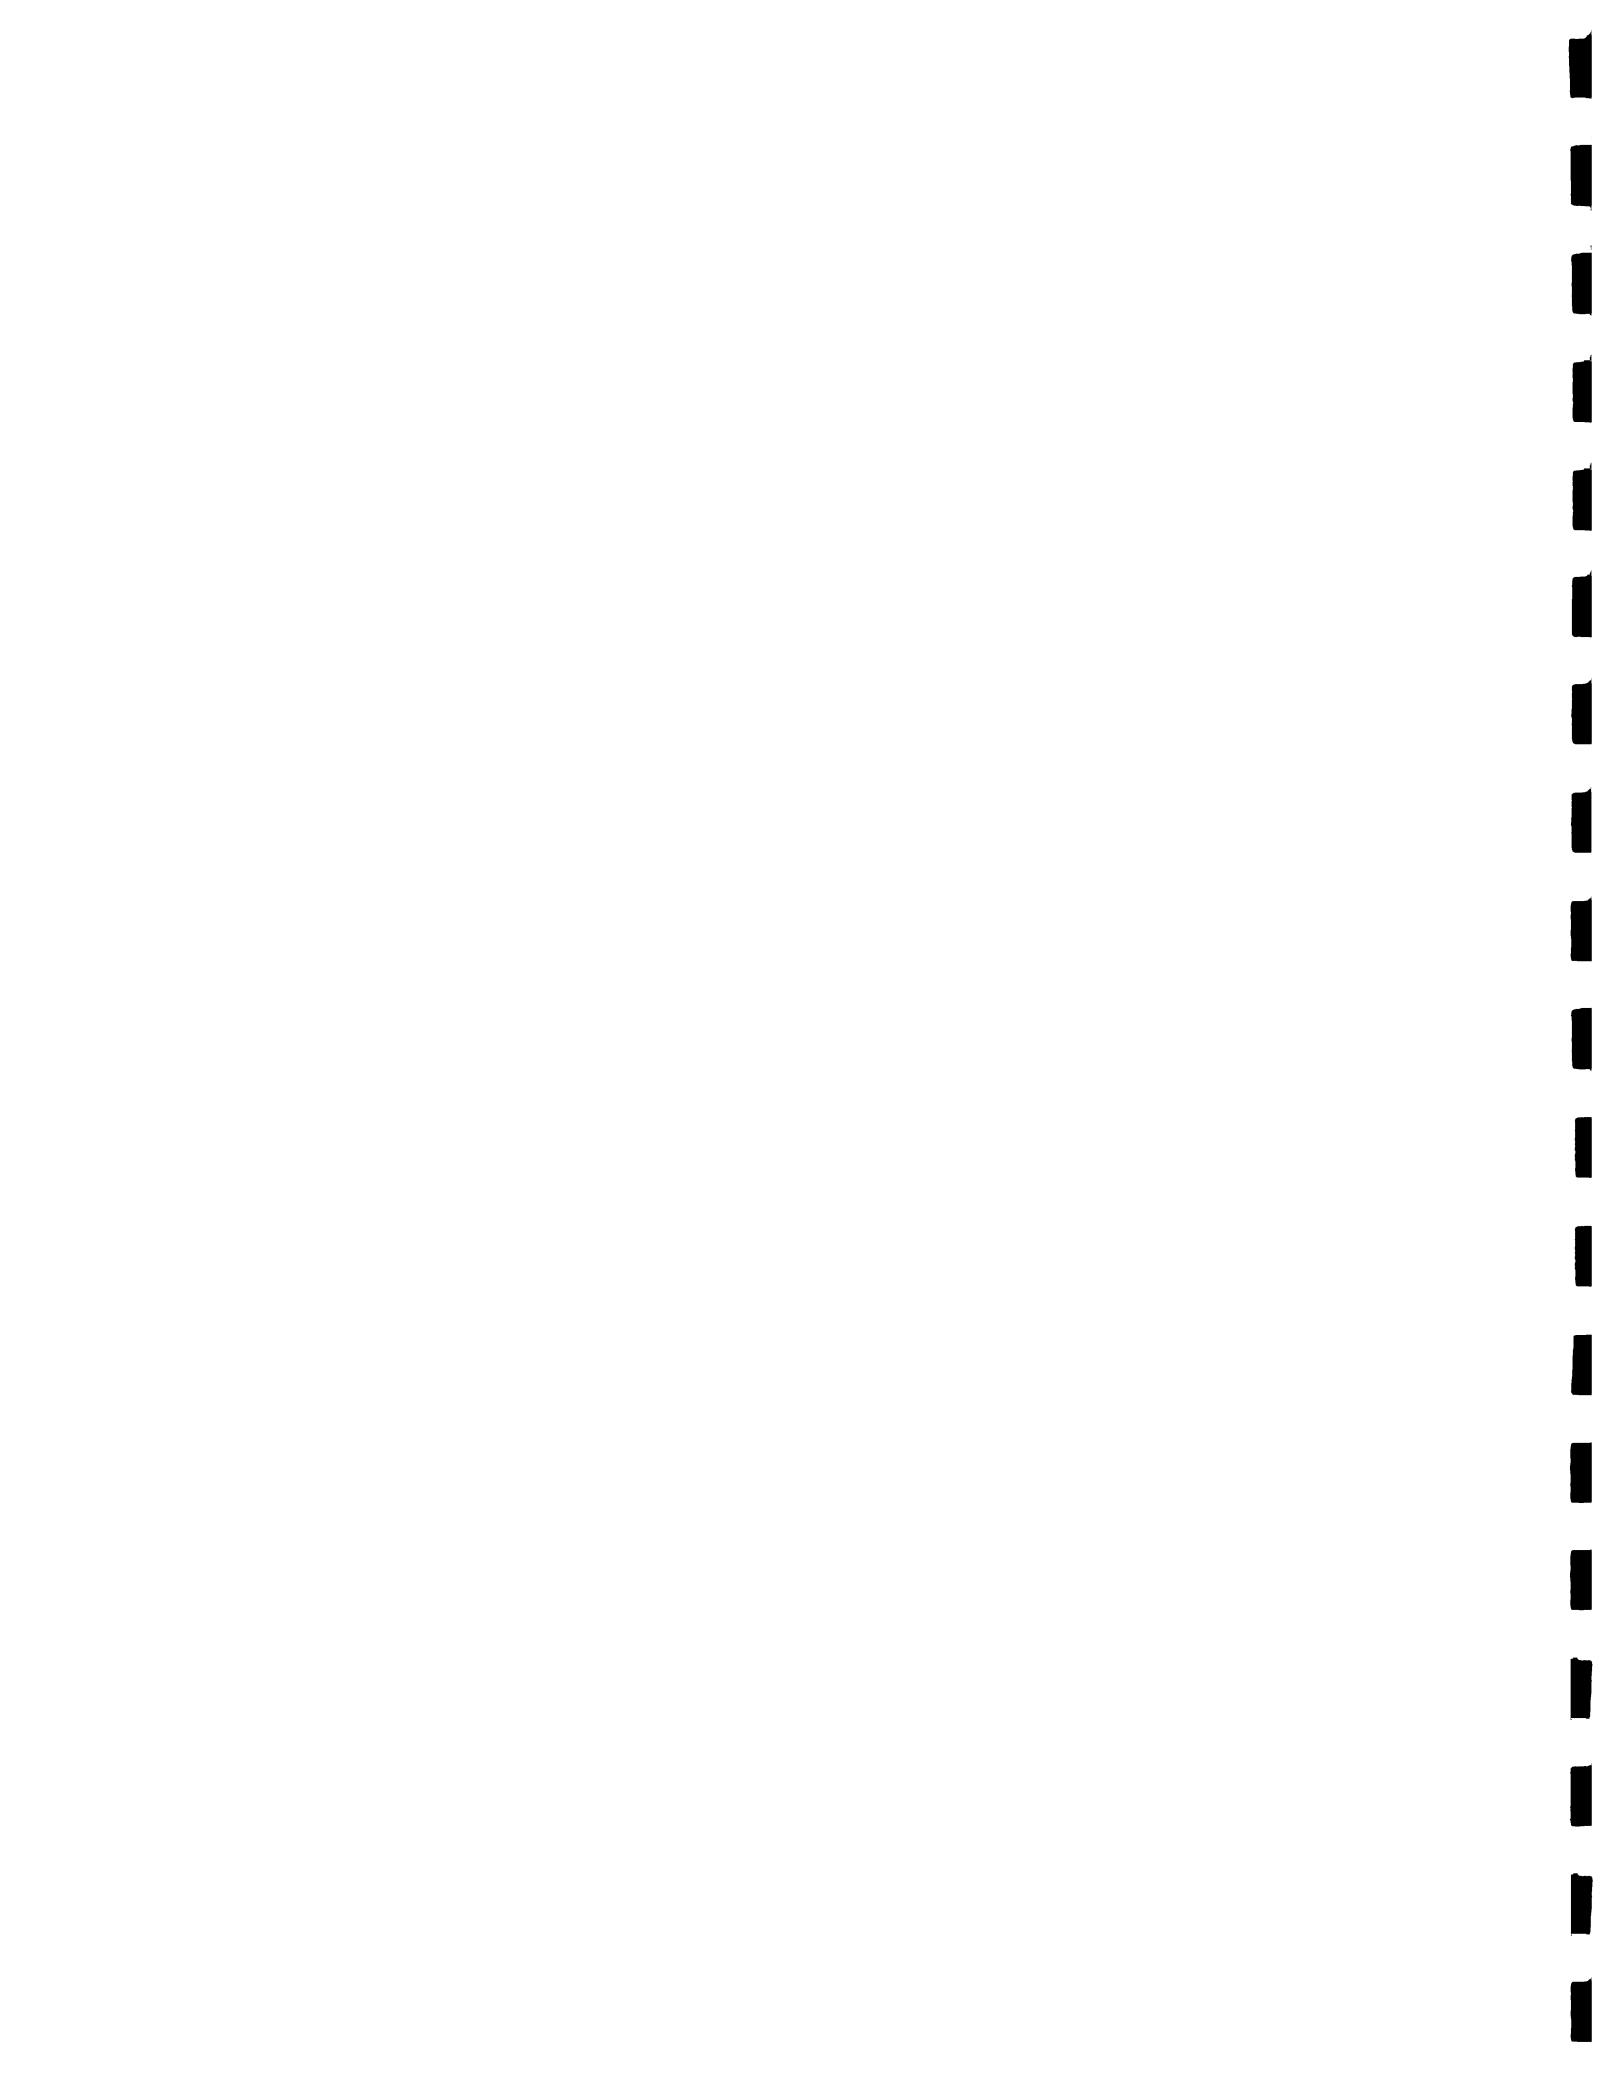

V. CALIBRACION DEL MODELO LLUVIA- ESCORRENTIA

No se hizo una calibración propiamente dicha, ya que no existían registros de caudales en la cuenca, sin embargo se utilizaron como control los caudales obtenidos de aforos esporádicos realizados a partir de 1976. Aunque se instaló una estación limnimétrica en El Millo en noviembre de 1984, algunos problemas de operación no permitieron el uso de los datos colectados para los fines del presente estudio.

Uno de los procesos más importantes en una cuenca como la estudiada es el escurrimiento aportado por el almacenamiento de aguas subterráneas, por lo que a partir de dos valores consecutivos del caudal cuidadosamente seleccionados se determinaron el coeficiente de recesión del almacenamiento de agua subterránea y el valor de la lámina almacenada para ser suministrado como valor inicial.

1. Cálculo del Coeficiente de Recesión del Agua Subterránea (CGW).

- Período del 30/11/84 al 27/01/85
- Lluvia del Período: 18.3 mm
- Ecuación de recesión: $q_t = q_0 \cdot K v^t$, donde
 - q_t = Caudal al cabo de un tiempo t , m³/s
 - q_0 = Caudal al tiempo cero, m³/s
 - K = Coeficiente de recesión
 - t = Tiempo transcurrido entre q_0 y q_t , en días

$$\ln q_t = \ln q_0 + t \ln k_r$$

$$\ln k_r = \frac{\ln q_t - \ln q_0}{t}$$

$$\ln k_r = \frac{\ln 0.731 - \ln 0.865}{58} = 0.002902$$

$$k_r = 0.9971$$

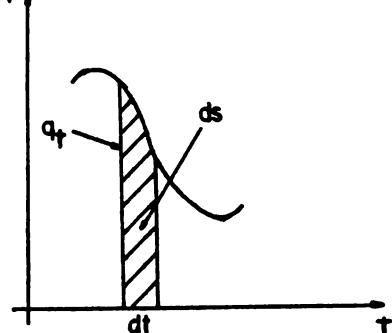

$$CGW = 1 - k_r$$

$$CGW = 0.00289$$

$$CGW = 0.0029$$

2. Cálculo del Almacenamiento de Agua Subterránea (GWS).

En la rama descendente del hidrograma se cumple

$$ds = q_t \cdot dt \quad ds = q_0 \cdot k_r^t \cdot dt;$$

$$\text{Integrando: } -S = q_0 \cdot \frac{k_r^t}{\ln k_r} \quad S = (q_0 \cdot k_r^t) / \ln k_r;$$

$$S = \frac{q_t}{-\ln k_r}$$

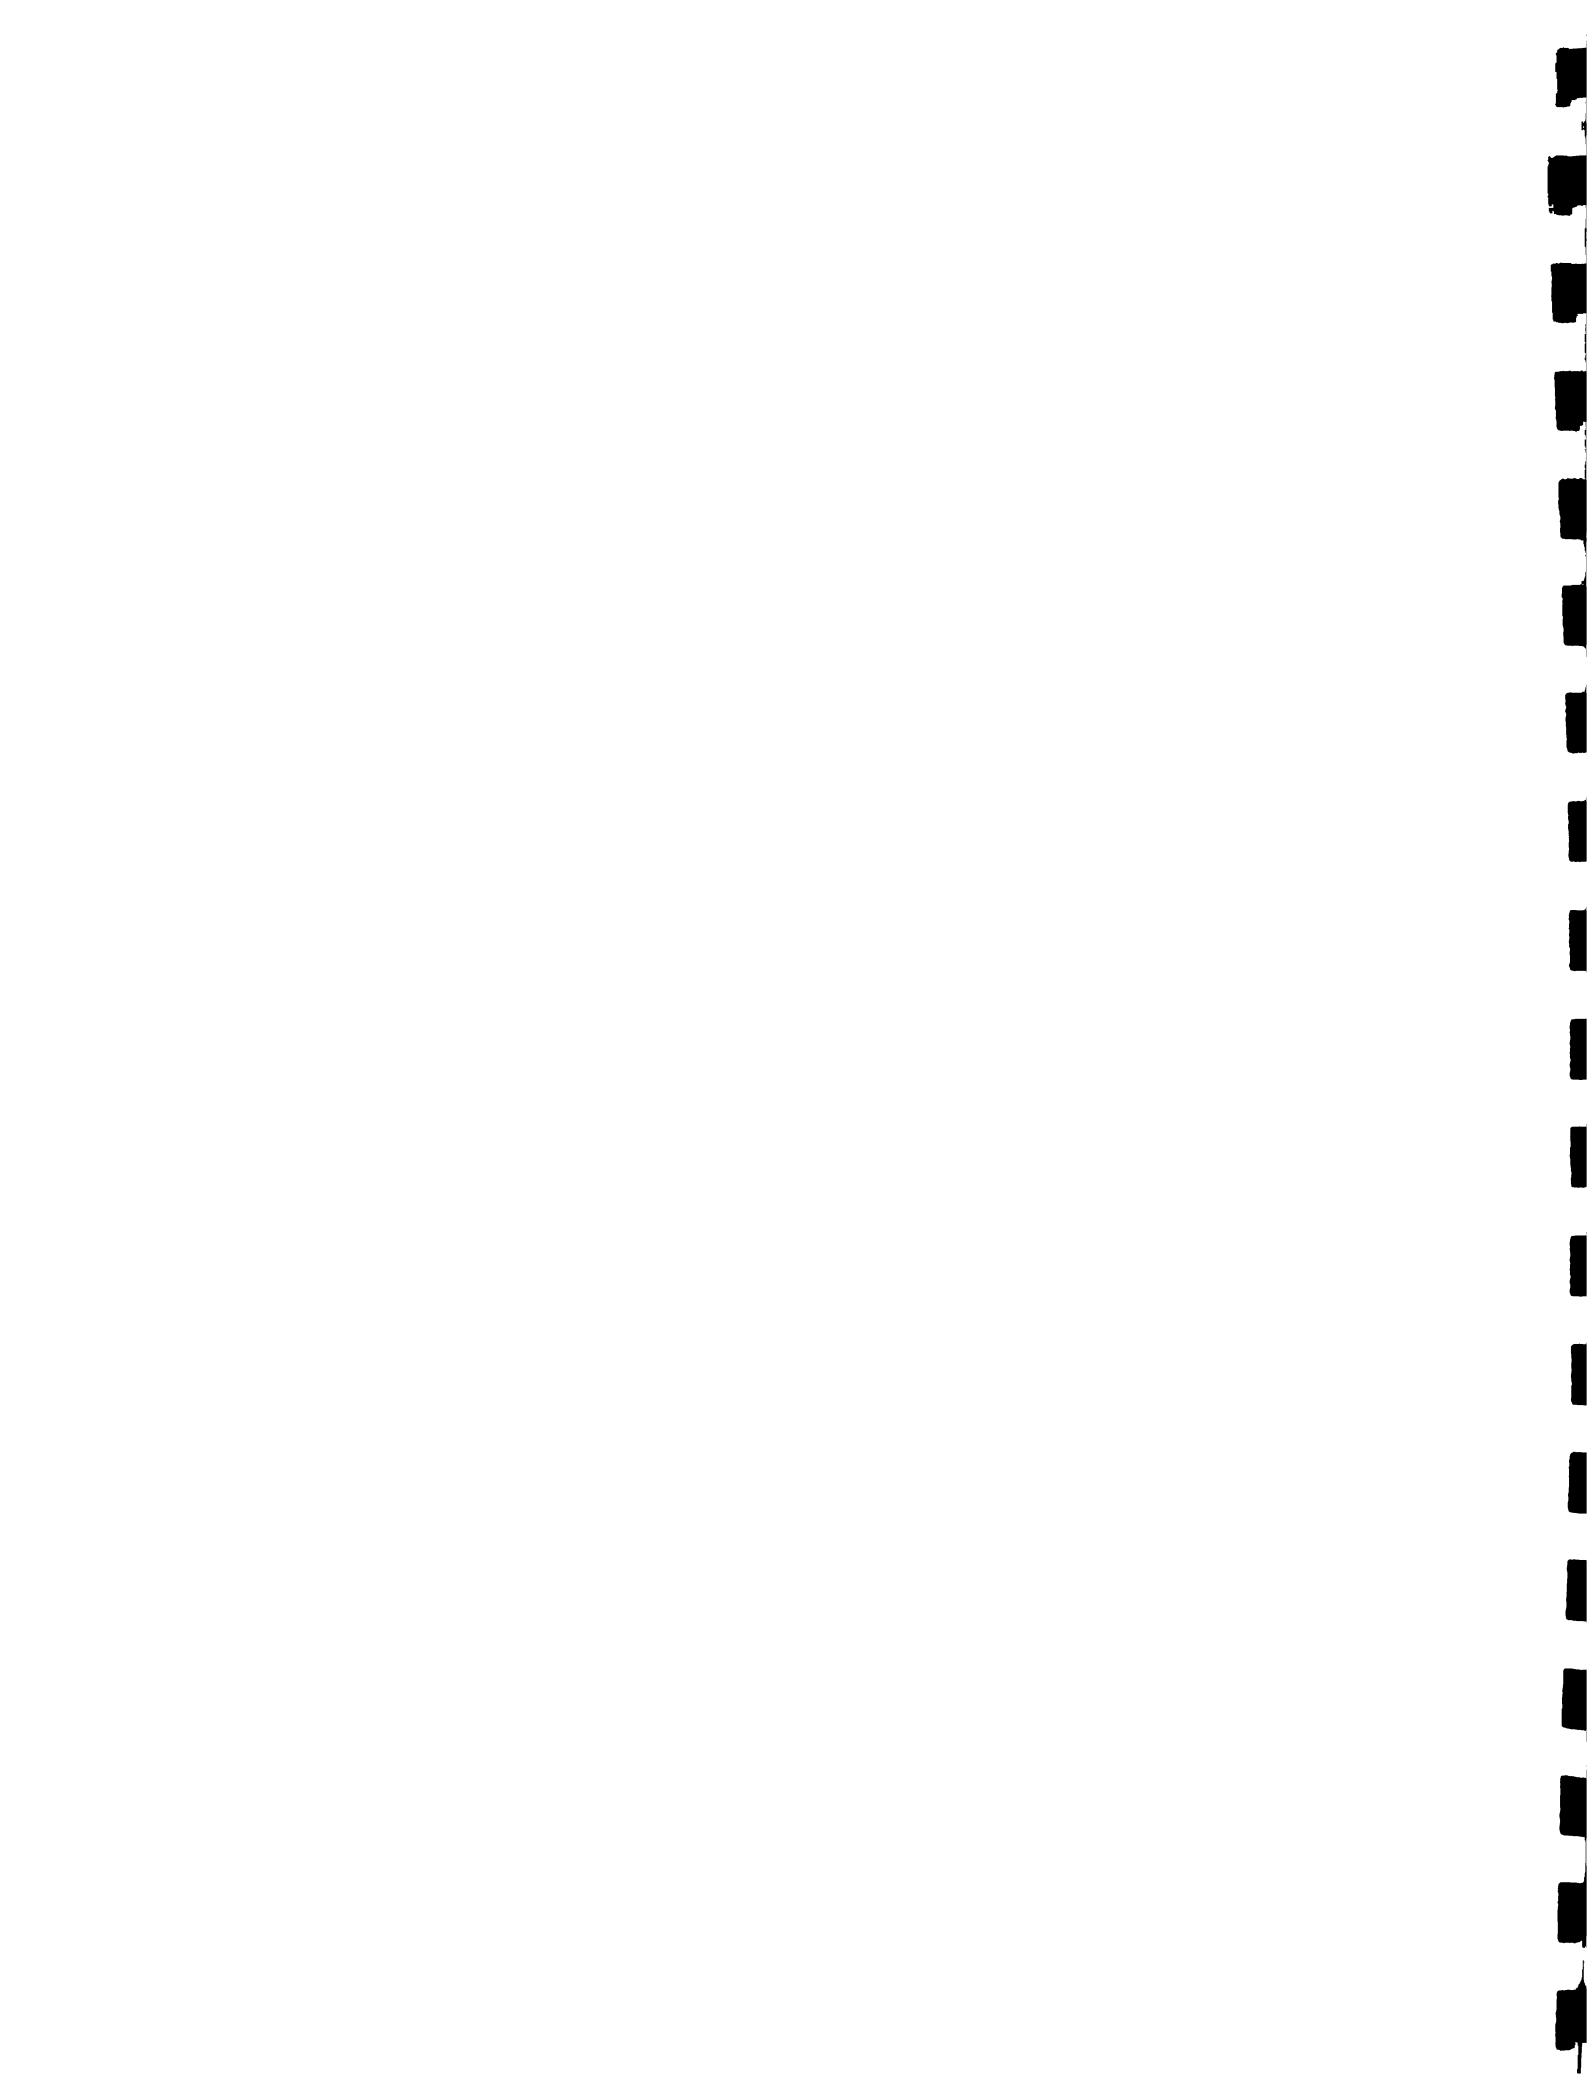

Como S es una lámina y Kr fue definido para un intervalo de un día, qt deberá ser expresado como lámina escurrida en un día.

$$qt(\text{mm}) = 0.731 (\text{m}^3/\text{s}) \times 86400 (\text{seg}) / 34.65 (\text{km}^2) \times 10^{-3} = 1.82$$

$$S = \frac{1.82}{0.002902}$$

$$S = 627.2 \text{ mm}$$

Los parámetros restantes fueron seleccionados como se describe a continuación:

3. UZSN fue seleccionado como 4 mm para reflejar la escasa cobertura sobre el suelo en el área de la cuenca.
4. LZSN. Se asumió un valor de 200.0 mm a partir de que el mayor almacenamiento de humedad se presenta como agua subterránea. Esta aseveración es corroborada por el tipo de vegetación presente en la mayor parte del área de la cuenca.
5. K3=0.4 considera la poca capacidad de la vegetación para extraer agua como transpiración.
6. Los demás parámetros fueron estimados a partir de experiencias anteriores con este tipo de modelo.

VI. RECONSTRUCCION DE LA SERIE DE CAUDALES

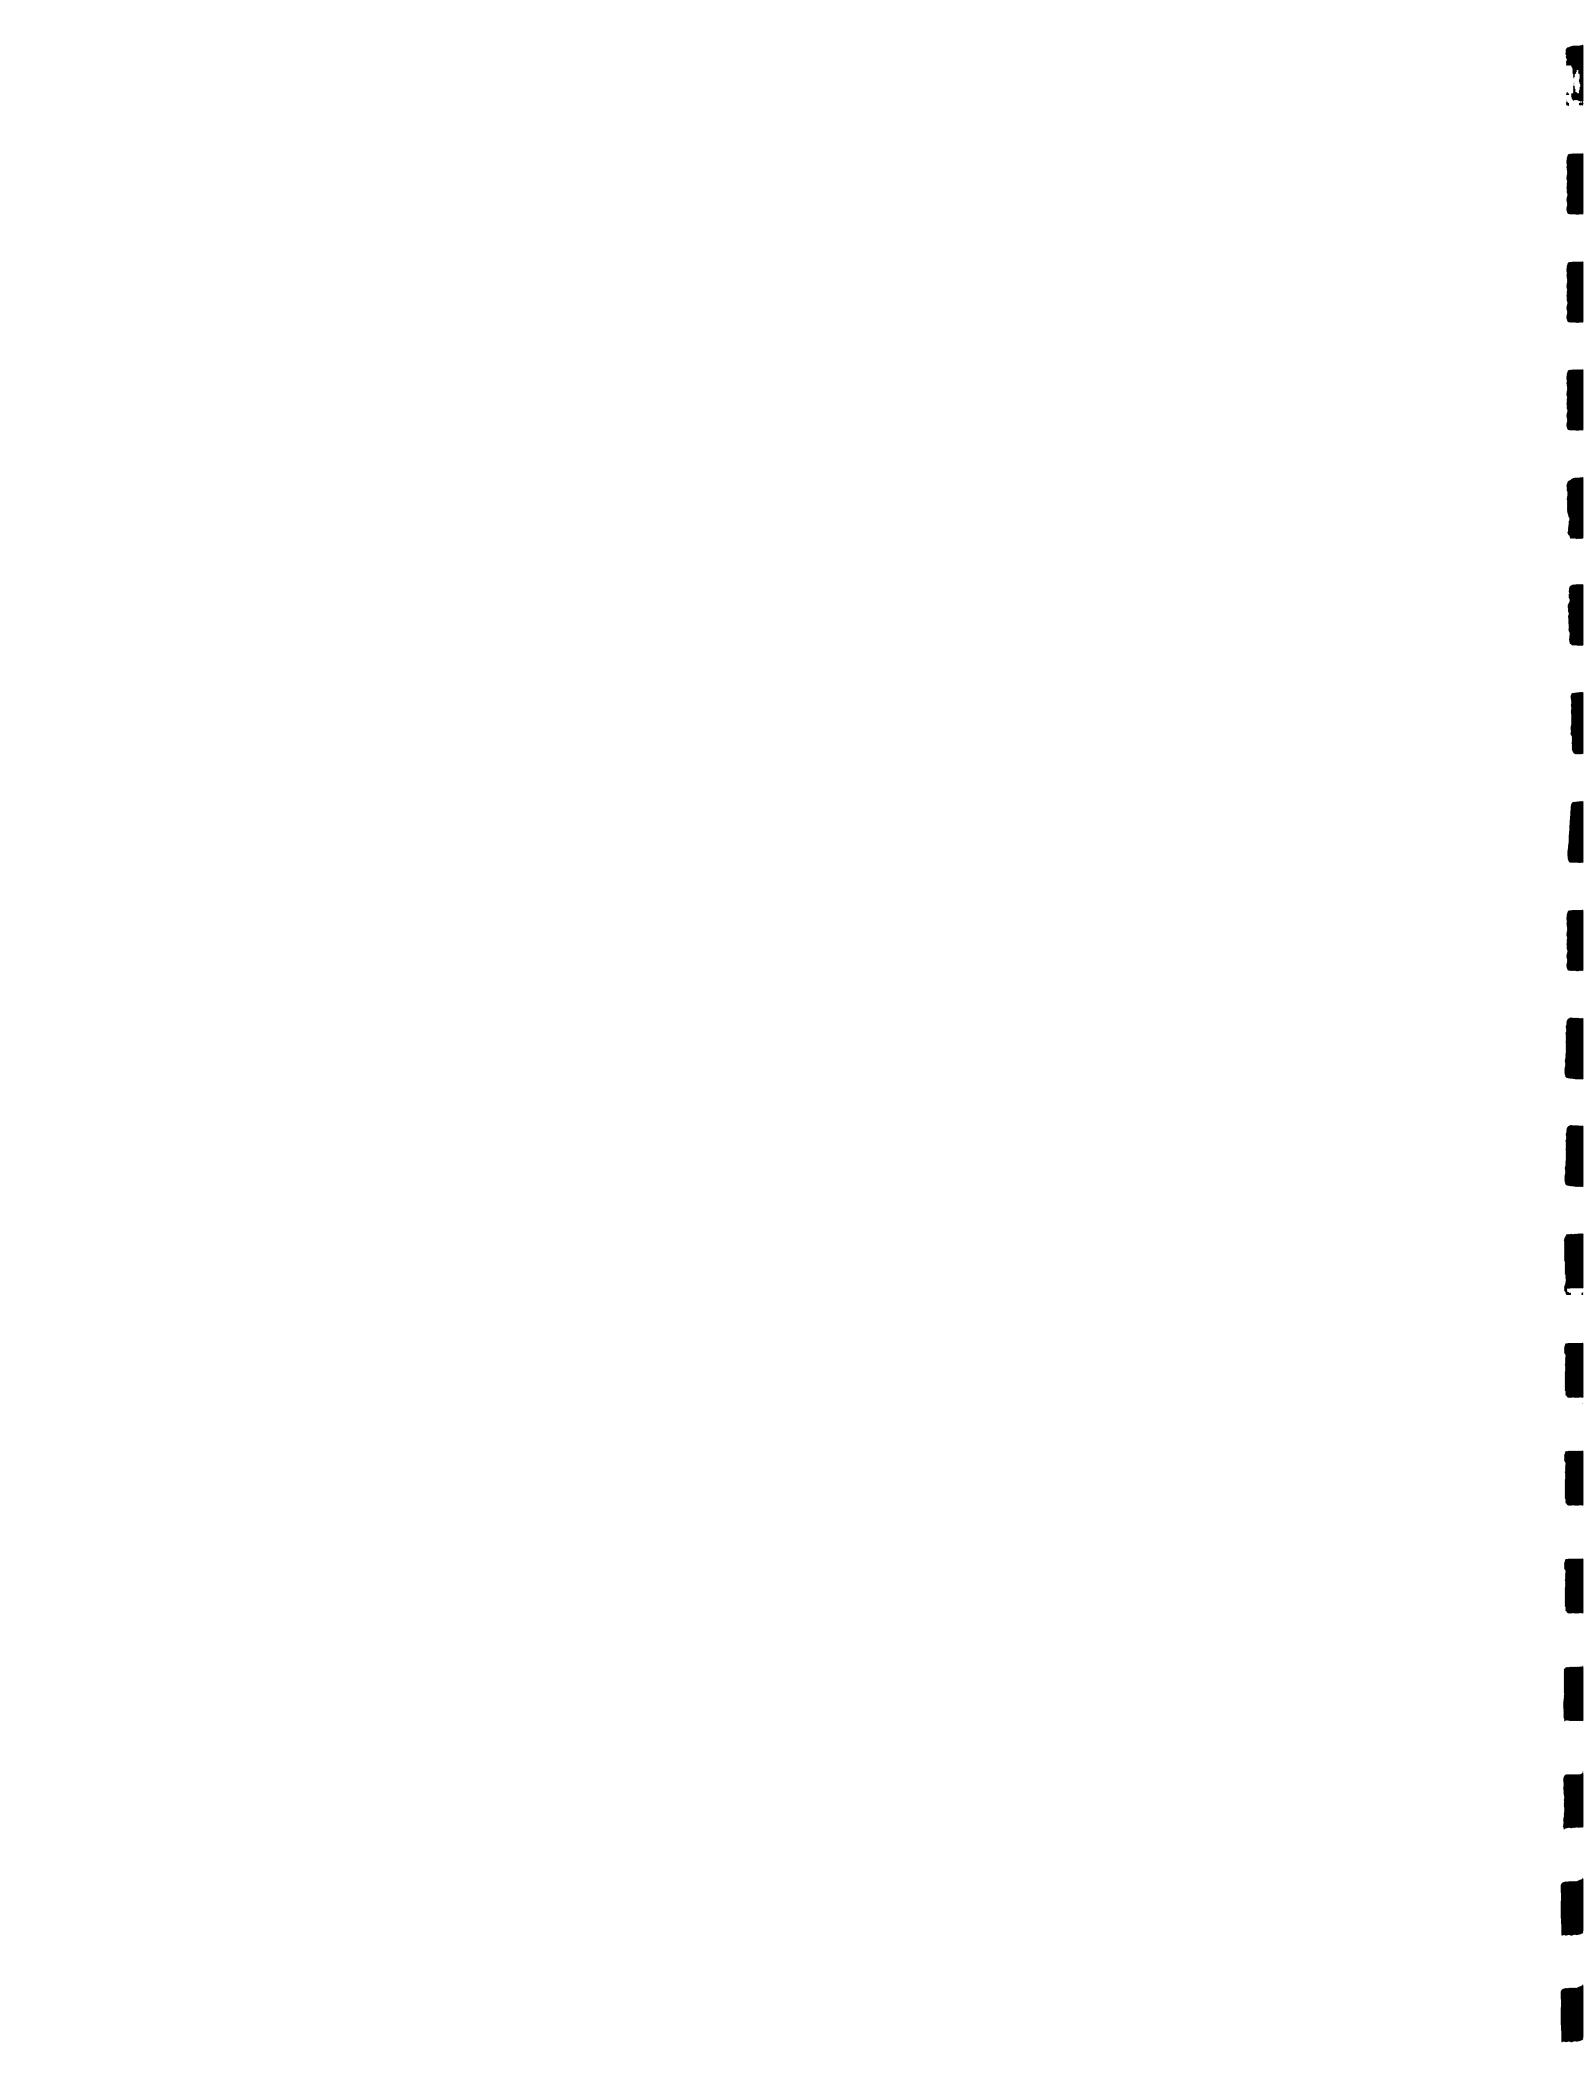

En el Cuadro 8 se comparan los caudales correspondientes a aforos esporádicos y los simulados por el modelo en la misma fecha. El Cuadro 9 y la Figura 5 presentan la curva de duración de caudales medios diarios y en el Cuadro 10 se presentan los caudales medios mensuales del período 1972-1984. Estos caudales fueron obtenidos a partir de la lluvia de Los Bolos modificada, la evaporación de tina "A" de Neyba modificada y el modelo lluvia-escorrentía.

Los caudales mínimos y máximos mensuales parecen consistentes con la poca información disponible. En el Anexo 3 se presentan los caudales medios diarios para el período indicado.

Existen algunos aspectos relevantes en los resultados de la calibración que se comentan a continuación.

1. El parámetro K_1 se fijó en 1.05, un valor bastante superior al calculado a partir del plano de isoyetas. Este resultado parece ser consecuencia del flujo con dirección noroeste-sureste en la región de la Sierra de Neyba, tal y como se estableció en la sección II.1.

2. Aunque es imposible lograr un ajuste "día por día" entre los resultados del modelo y los aforos esporádicos, la tendencia general entre ambas series se considera aceptable.

FIGURA N° 5

RIO MAJAGUAL EN EL MILLO
CURVA DE DURACION DE CAUDALES MEDIOS DIARIOS SIMULADOS

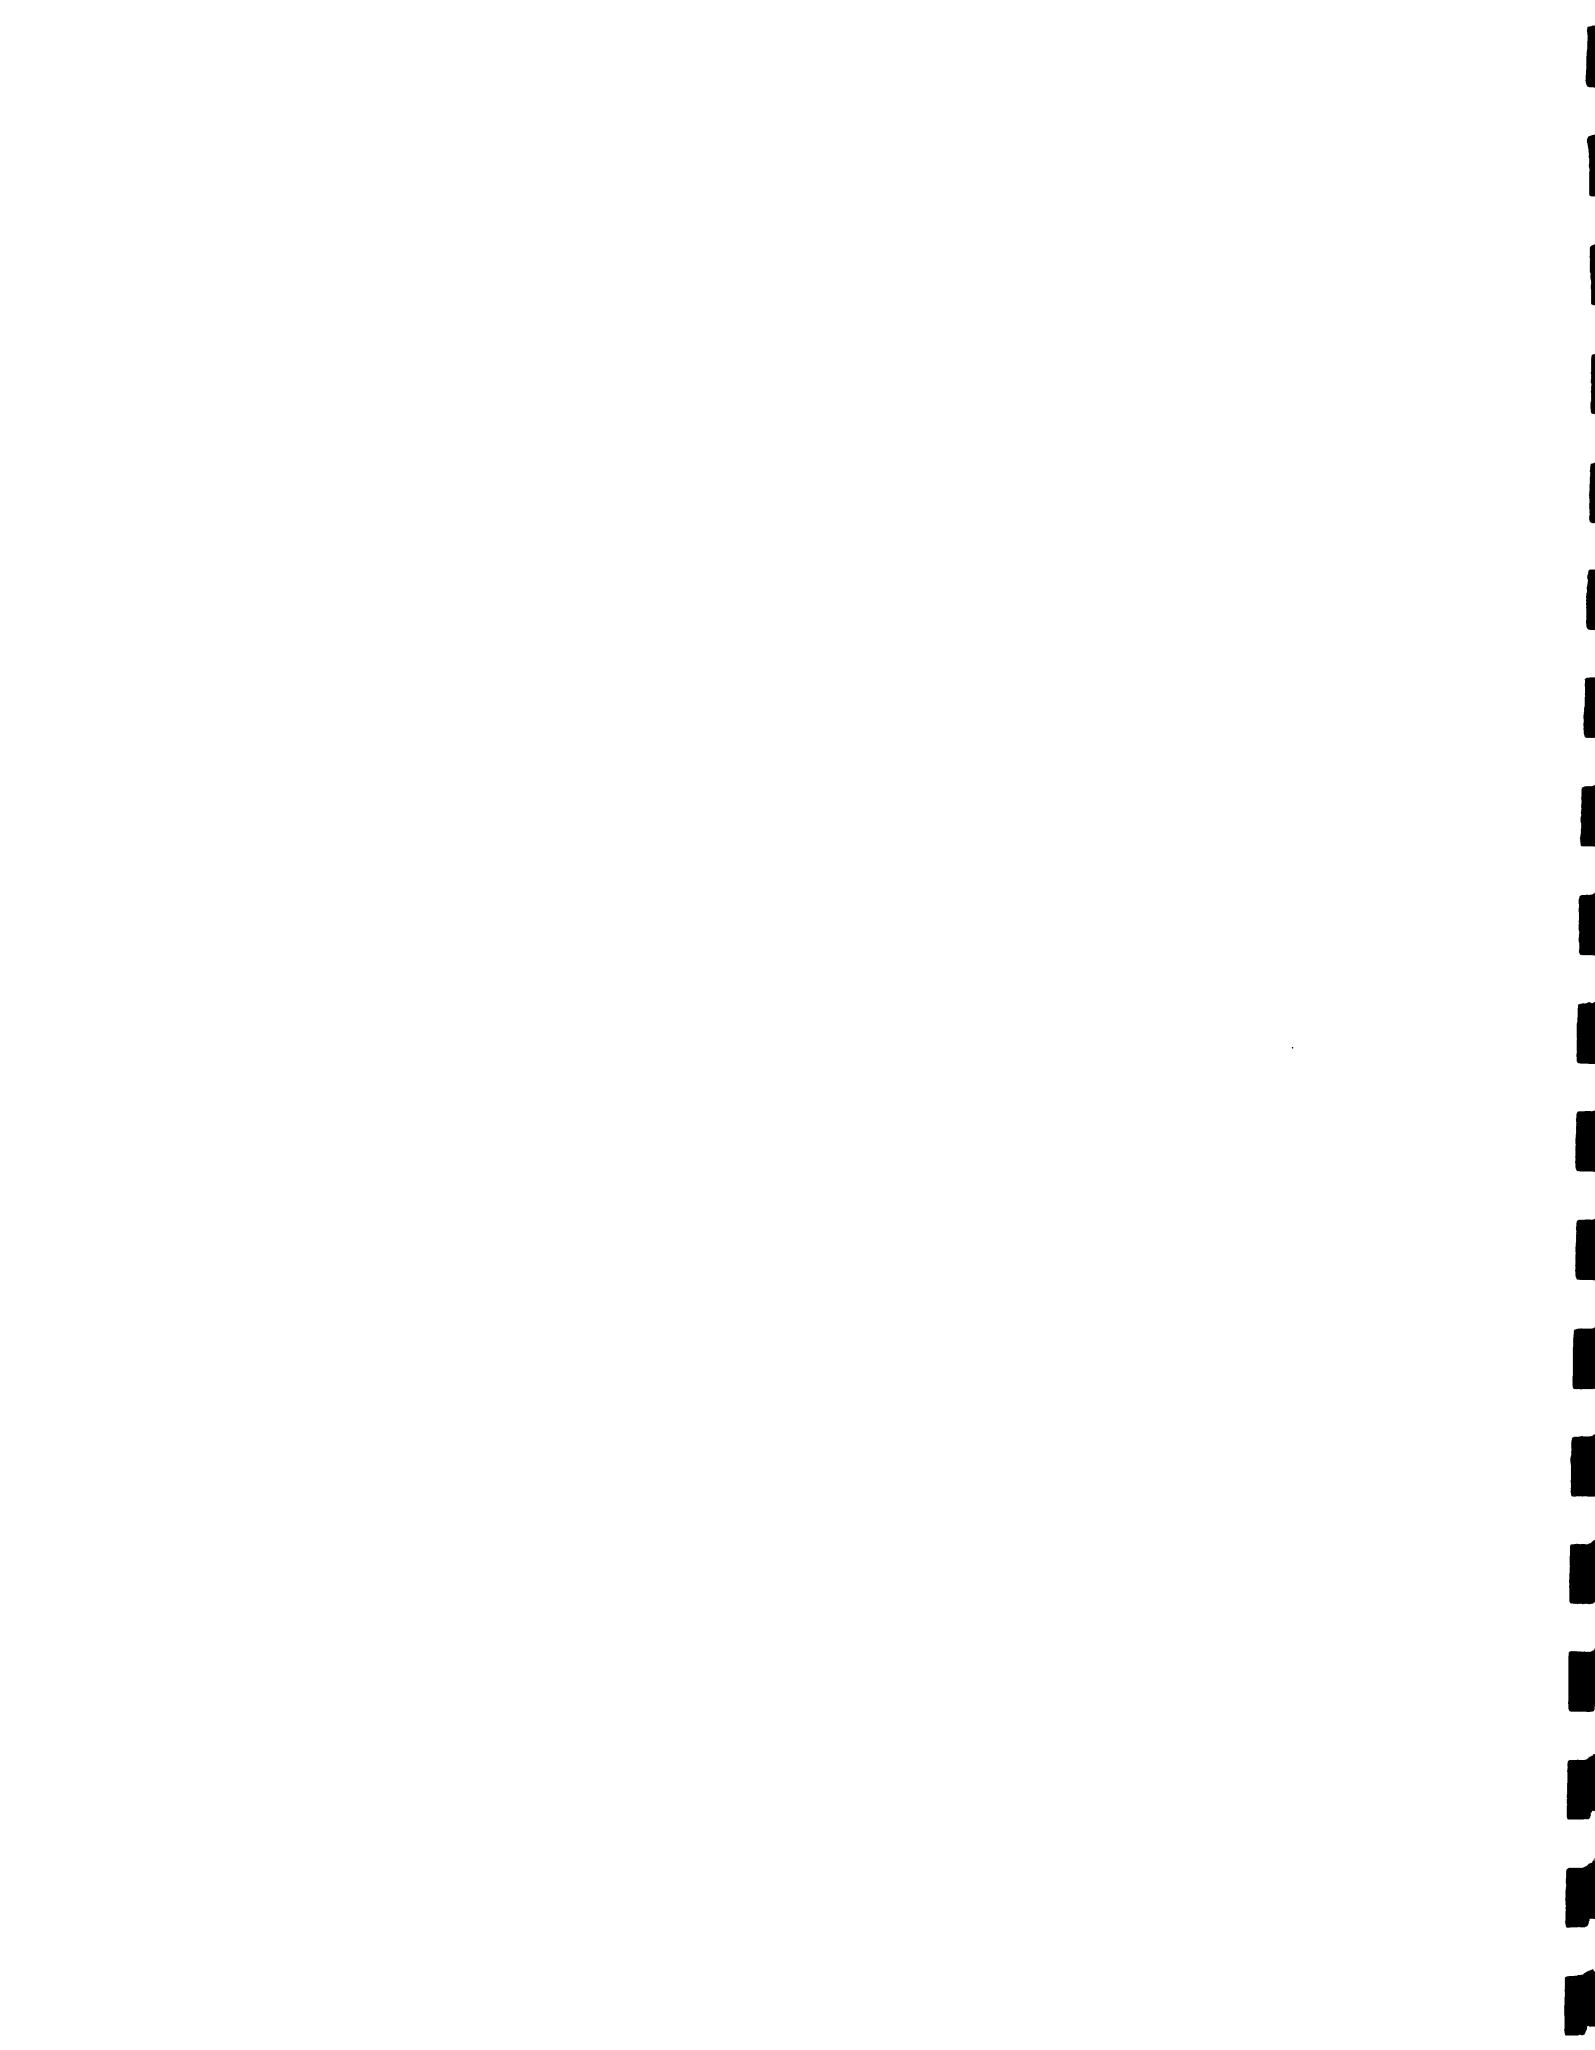

% DEL TIEMPO EN QUE EL
CAUDAL ES IGUALADO O
EXCEDIDO

3. La distribución de los caudales en el tiempo que sintetiza la curva de duración de caudales es típica de un sistema con una componente importante de aguas subterráneas.

4. Aunque el modelo no logra reproducir la crecida producida por el paso del huracán David y la tormenta Federico en 1979, ello no lo invalida como herramienta para efectuar la transformación lluvia-escorrentía para las condiciones normales, que son las que interesan en el análisis de un sistema de riego.

VII. CALIDAD DEL AGUA

Se tomaron algunas muestras de agua en el sitio de Milló, con el propósito de determinar la aptitud de la misma para riego. Los análisis de laboratorio indicaron que las aguas cumplen con todos los requerimientos establecidos, como se indica en el Cuadro 11.

Debe destacarse que el período de toma de las muestras comprende el estiaje, cuando puede manifestarse con mayor intensidad la presencia de sólidos disueltos que afectan negativamente la calidad del agua.

VIII. CONCLUSIONES Y RECOMENDACIONES

1. El análisis de la precipitación y demás factores climáticos en el área de la cuenca a partir de las extrapolaciones discutidas constituyen un estimado aceptable para los fines del Proyecto.
2. El desarrollo del modelo lluvia-escorrentía y su aplicación para reconstruir la serie de caudales del río Majagual en El Millo constituyen un procedimiento adecuado para fines de diseño y operación del Sistema de riego.
3. La calidad del agua es buena, por lo que su uso racional para riego no implica problema alguno.
4. Se recomienda reforzar el sistema de medición hidropluviométrica instalado al inicio de los estudios, así como reinstalar la estación climática que operó en Neyba hasta noviembre de 1980.
5. Se recomienda implantar un programa de protección de la cuenca, como una forma de garantizar la producción sostenida de agua y prevenir el aumento de la tasa de erosión y consecuente sedimentación.

ANEXO 2: DESCRIPCION DEL MODELO

II.1 FUNCIONES DEL MODELO.

En la Figura 4, se muestra el esquema del modelo. A continuación se describen los aspectos conceptuales más relevantes en la formulación del mismo para la transformación lluvia-escorrentía.

a)- Lluvia sobre la Cuenca: Como los registros de lluvia corresponden a la ocurrencia puntual del proceso, se requiere un factor de corrección para que dichos registros puedan ser representativos de la ocurrencia de la lluvia sobre el área de la cuenca. Dicho factor se establece como

$$K_1 = \frac{\text{Precipitación Areal}}{\text{Precipitación Puntual}}$$

La precipitación areal se obtiene generalmente de un plano de isoyetas.

b)- Evapotranspiración Potencial. Se estima a partir de datos de tina "A", a los que se aplica un coeficiente de tanque, C_t , y un factor para tomar en cuenta el caso común de que la tina está fuera del área de la cuenca, F_g .

$$ETP = E(\text{tina}) \times C_t \times F_g$$

c)- Areas Impermeables. Siempre existe una fracción del área de la cuenca (CIMP) que por la condición de saturación de la humedad del suelo convierte en escorrentía directa toda la precipitación que recibe.

$$ESCI = RF \times CIMP$$

d)- Infiltración. Este proceso es tratado en varios pasos:

-Se determina el potencial de infiltración considerando las características fijas (pendiente, uso de la tierra, tipo de suelo) y las variables (humedad del suelo)

$$FMAX = INFIL / ((BZANT / BZMAX)^2) \times 2 ,$$

Donde:

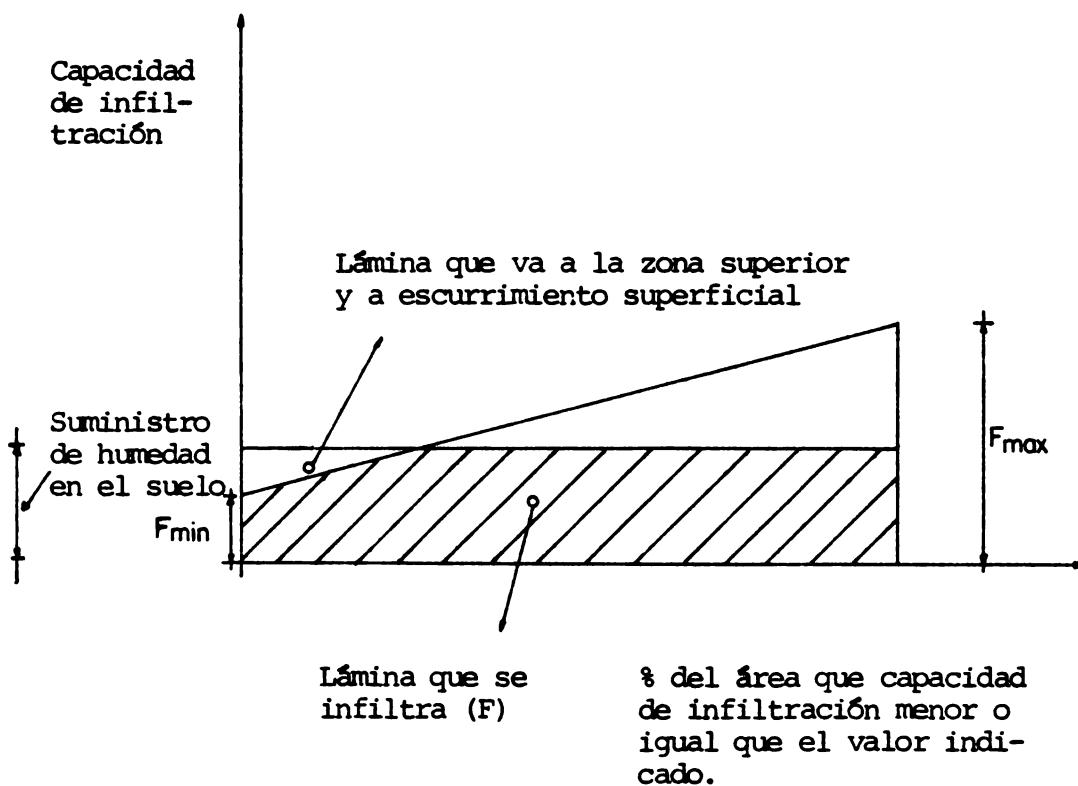

FMAX: Capacidad máxima de infiltración en algún punto de la cuenca.

BZANT: Lámina almacenada en la zona inferior al final del día anterior.

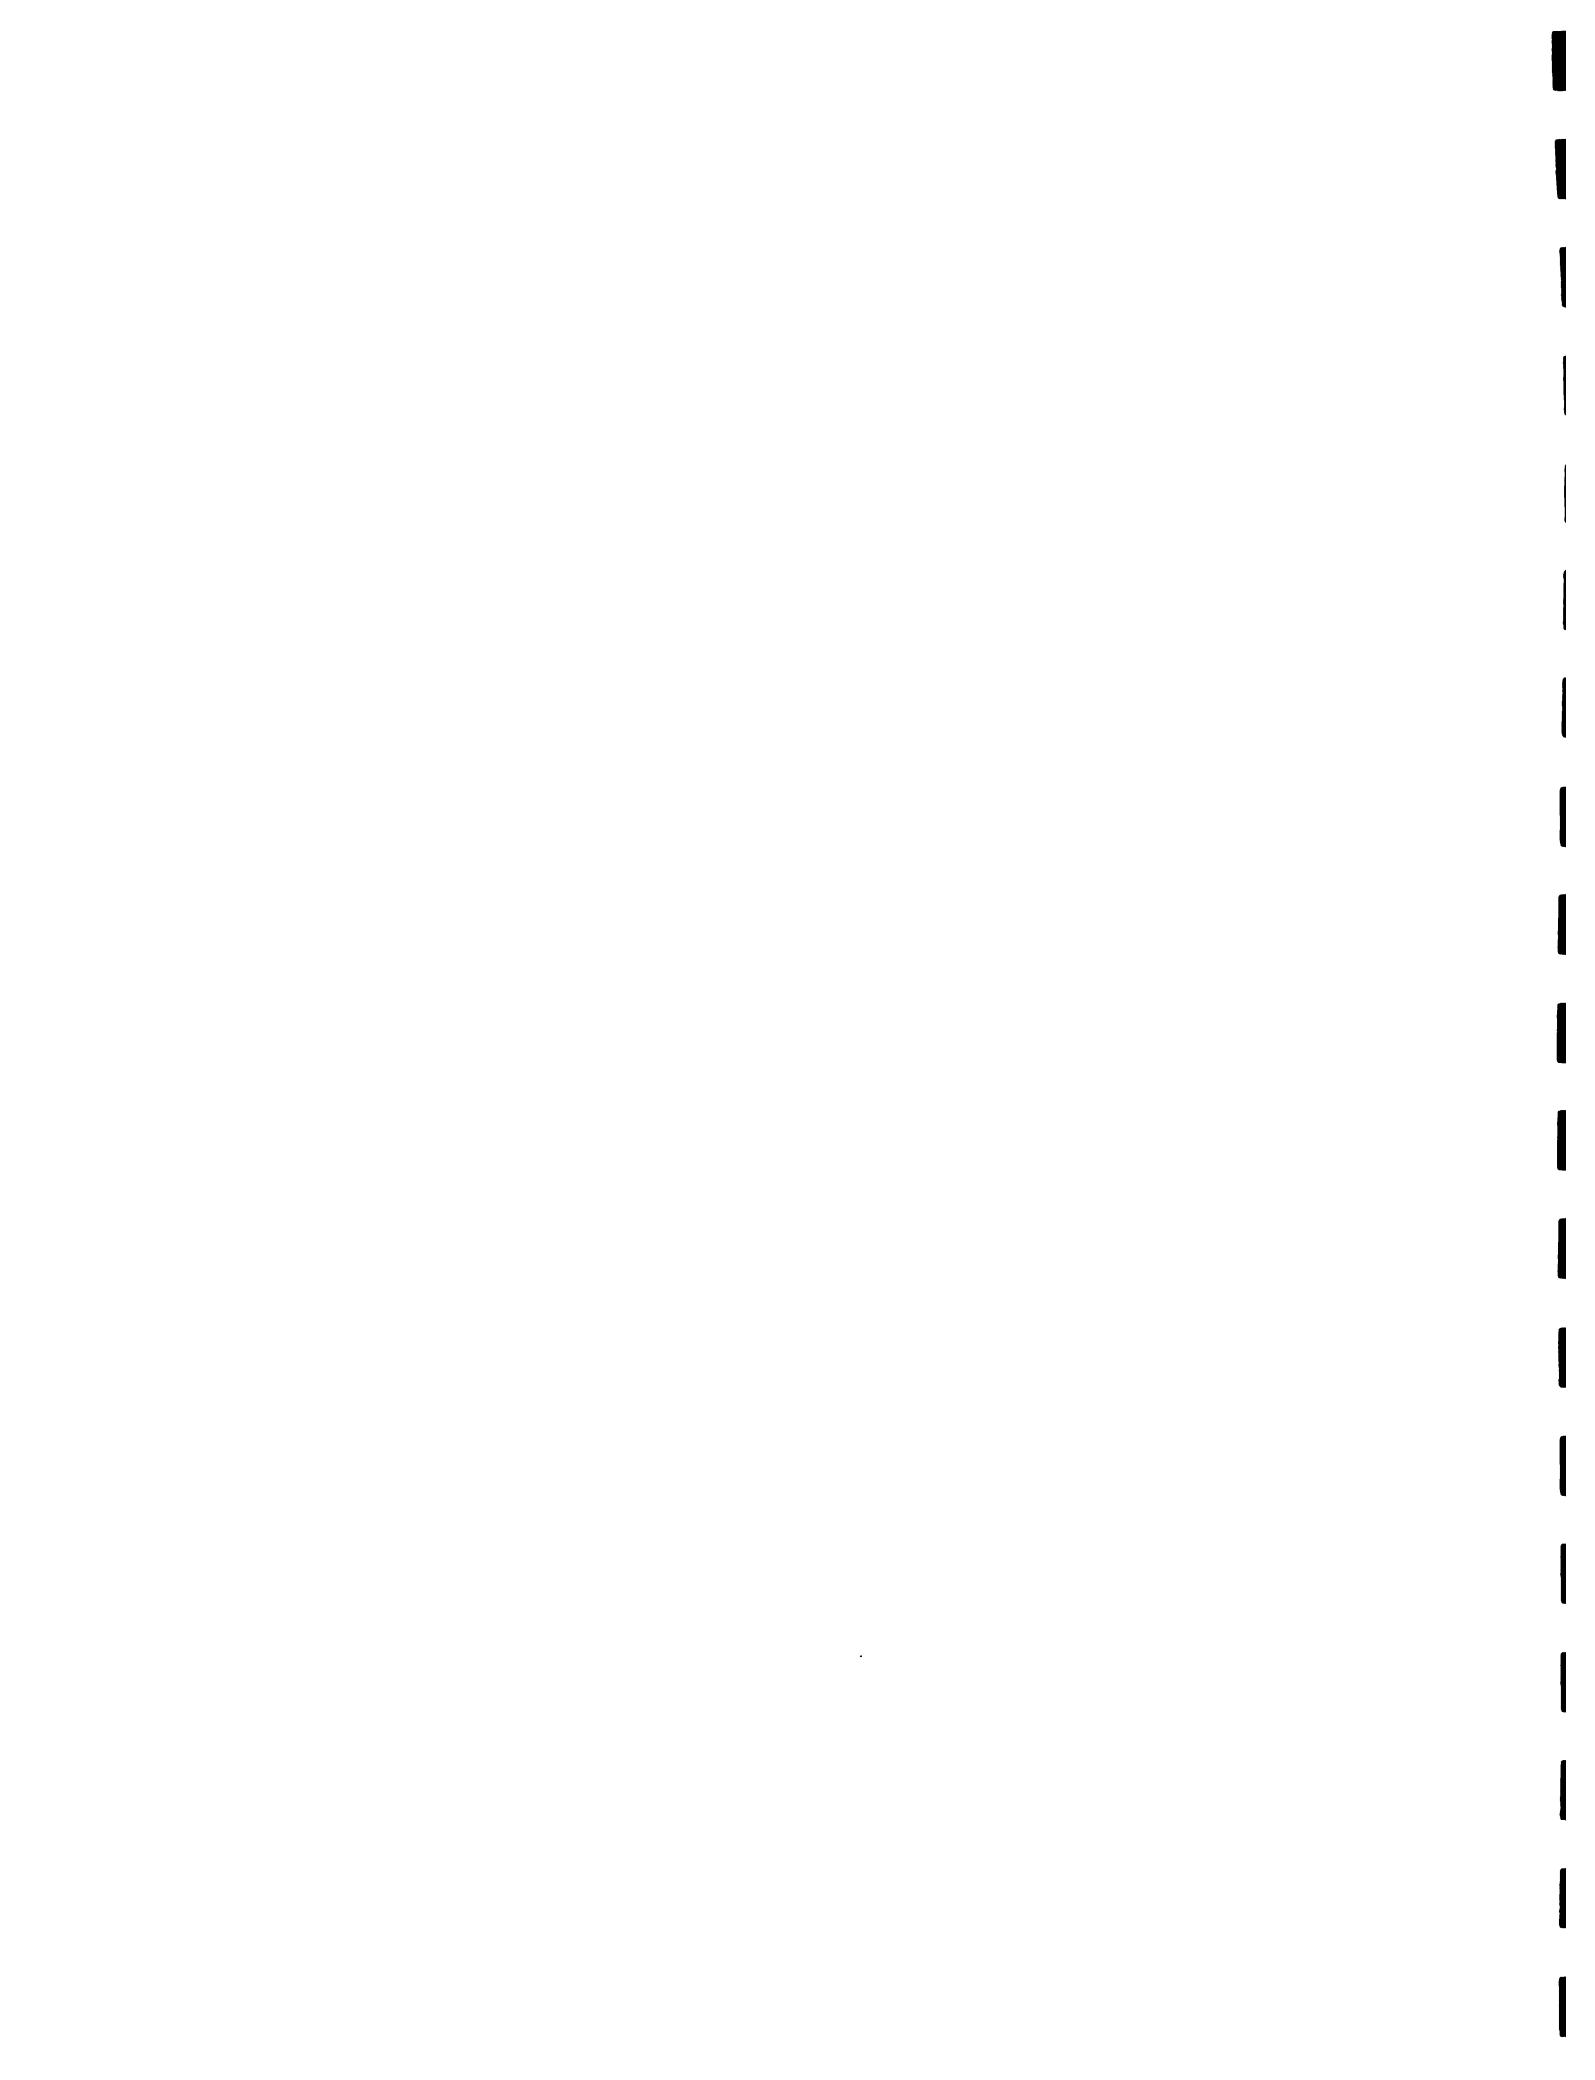

BZMAX: Almacenamiento nominal de la zona inferior. Es un parámetro que permite una respuesta suave del modelo a los cambios en el suministro de humedad.

-Una vez determinado el potencial de infiltración de la cuenca se calcula la lámina infiltrada mediante una función que puede representarse gráficamente como sigue:

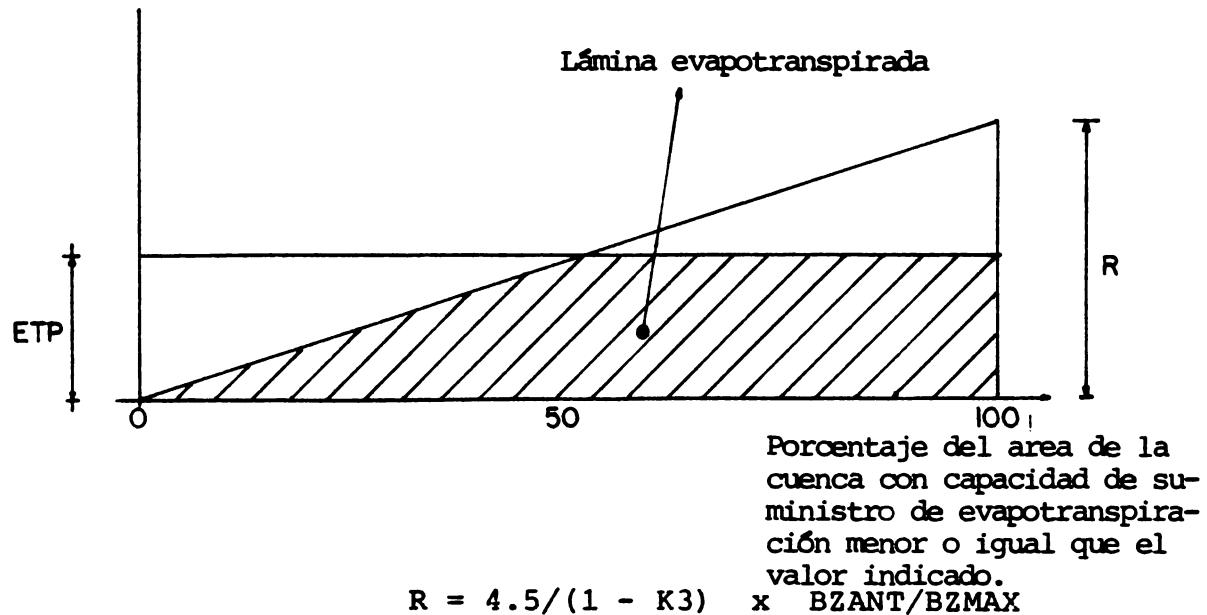

FMIN es la tasa mínima de infiltración en algún punto de la cuenca y es un valor fijo. El tratamiento anterior implica la asunción de una tasa de infiltración variable en los diferentes puntos de la cuenca, - siendo FMIN y FMAX los valores extremos.

- e)- Almacenamiento de la Zona Superior. La lámina que no se infiltra queda en la superficie y es retenida por las depresiones del suelo, constituyendo el almacenamiento de la zona superior. Cuando se ha agotado la capacidad máxima de este almacenamiento (UZMAX) el agua restante se destina al escurrimiento superficial. Un 20% de este resto se considera infiltración retardada que se agrega a la infiltración calculada previamente. El almacenamiento de la zona superior es agotado por la evapotranspiración a la tasa potencial.
- f)- Almacenamiento de la Zona Inferior. Es el que representa el almacenamiento de la zona no saturada del suelo y que suministra humedad a las plantas para el proceso de transpiración. Se asume que una fracción de la lámina total infiltrada dada por $(1-BZANT/BZMAX)$ alimenta este almacenamiento o si la fracción es menor que cero se asume que un 5% de la infiltración alimenta el almacenamiento. Este almacenamiento es agotado por la evapotranspiración a una tasa variable determinada de manera similar a la lámina infiltrada.

Donde: K_3 es un parámetro que representa la capacidad de la cobertura vegetal para extraer humedad del suelo.

g)- Agua Subterránea. La parte de la lámina total infiltrada que no es retenida en la zona inferior alimenta el almacenamiento de agua subterránea. Este almacenamiento entrega continuamente una lámina proporcional a la lámina almacenada

$$QGW = CGW \times GWS ,$$

Donde:

QGW: Lámina entregada.

CGW: Coeficiente de recesión del agua subterránea.

GWS: Lámina almacenada.

h)- Tránsito de Caudales. Las láminas de escurrimiento aportadas por las áreas impermeables, el escurrimiento superficial y escurrimiento subterráneo son convertidas a caudal tomando en consideración el área de la cuenca y el intervalo de análisis que para el presente caso es de un día.

Este caudal es transitado a través de la cuenca y el sistema de cauces usando el método hidrológico desarrollado por C.O. Clark y cuya expresión matemática es

$$QRCFS = CZ \times QCFS + C1 \times QCFSANT + C2 \times QRCFSANT$$

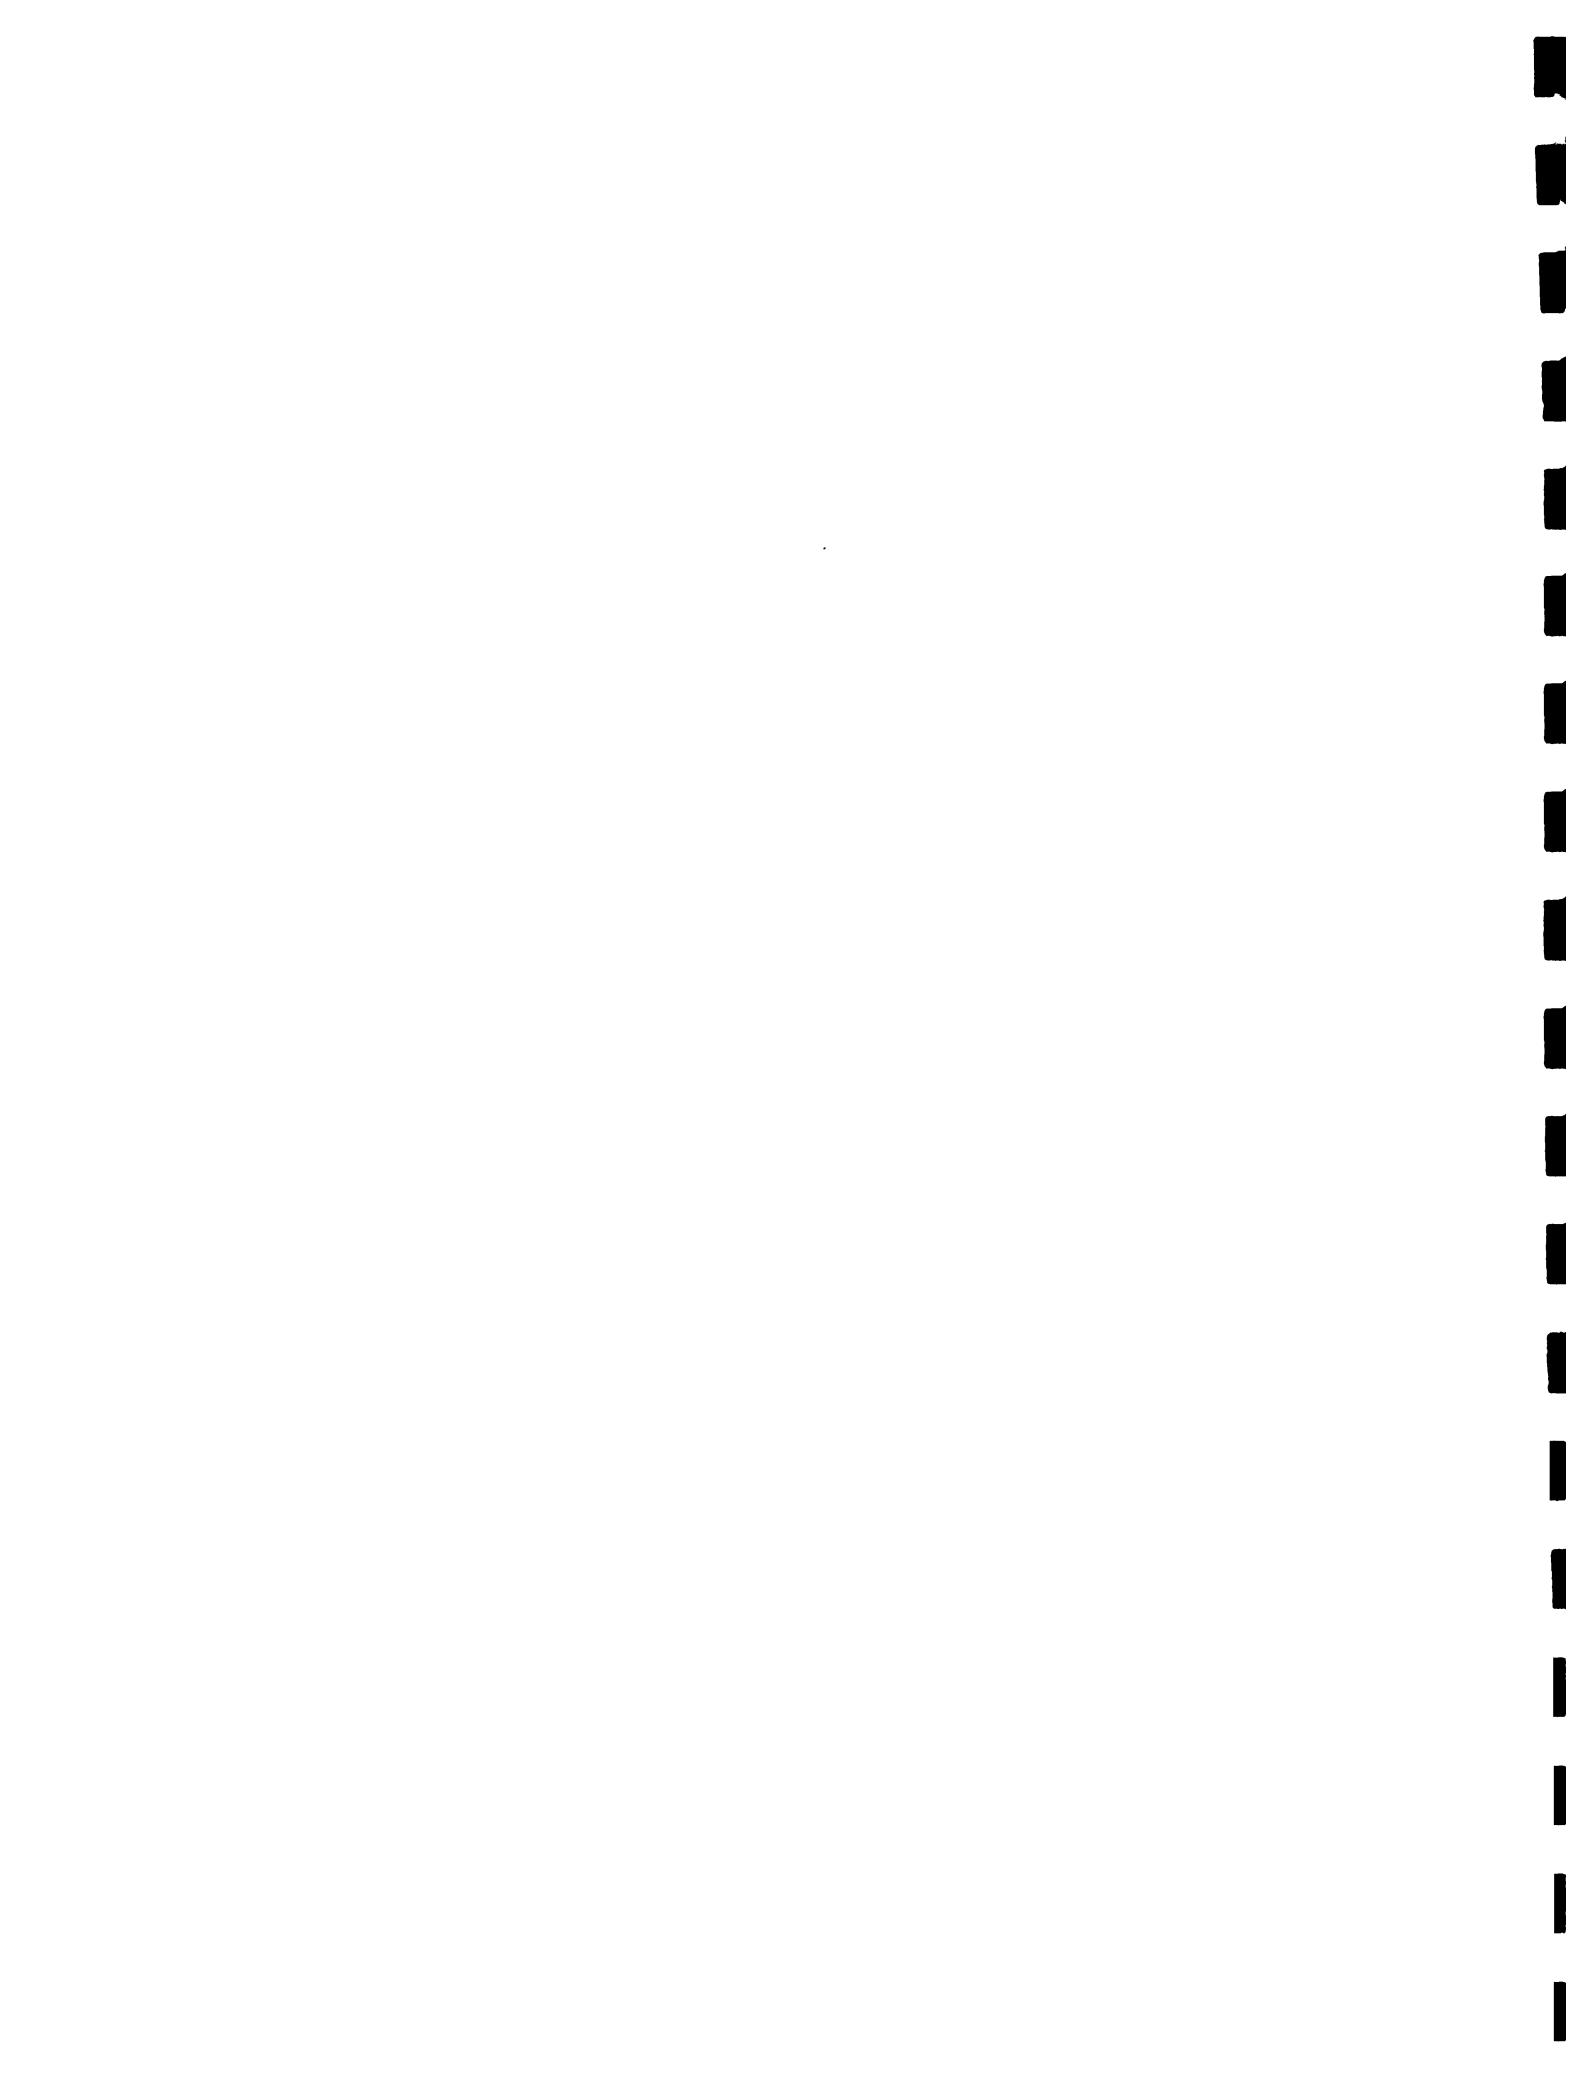

Donde:

C0, C1 y C2:son los coeficientes de tránsito

QCFS : es el caudal entrante del día en análisis
(I1)

QCFSANT : es el caudal entrante del día anterior
(I2)

QRCFSANT : Es el caudal transitado del día anterior
(O2)

II. 2 ENTRADAS.

Las entradas del modelo de simulación hidrológica utilizado para realizar la transformación lluvia-escorrentía pueden clasificarse en iniciales y continuas.

a) - Entradas Iniciales. Son aquellas que deben suministrarse al inicio de una corrida y que incluyen los parámetros que representan las características fijas de la cuenca y los valores de los almacenamientos. Estas entradas se describen a continuación, con el nombre con que aparecen en el listado del programa de computación escrito en lenguaje BASIC.

- MESIN : Mes en que se inicia la corrida
- NANIN : Año en que se inicia la corrida
- MEFIN : Mes en que termina la corrida
- NAFIN : Año en que termina la corrida
- CAL : Opción para entrar caudales observados. Si 0 no se entran; si 1 se entran.

- PARAMETROS -

- AREA : Área de la cuenca, en Km²
- K1 : Relación de la lluvia areal (sobre la cuenca) a la lluvia puntual en el sitio de registro.
- AJETIN : Relación de la evapotranspiración potencial a la evaporación de tina "A" y corrector de esta última por diferencia de localización con el área de la cuenca.
- CIMP : Fracción del área que puede considerarse impermeable (generalmente por saturación) conectada al sistema de cauces.
- CGW : Coeficiente de recesión del almacenamiento de agua subterránea, sobre base diaria.
- UZMAX : Capacidad máxima del almacenamiento de la zona superior.
- FMIN : Tasa mínima de infiltración en el área de la cuenca.
- INFIL : Tasa de infiltración que refleja las características fijas de la cuenca sobre la capacidad de infiltración.
- BZMAX : Valor nominal del almacenamiento de la zona inferior.

- CZ, C1 : Coeficientes de tránsito de los caudales a través de la cuenca y el sistema de cauces, según el método de C.O. Clark.
- K3 : Índice de la capacidad de la cobertura vegetal para extraer humedad del suelo.

-VALORES INICIALES-

- UZIN : Almacenamiento inicial de la zona superior (mm)
- BZIN : Almacenamiento inicial de la zona inferior (mm)
- GWSIN : Almacenamiento inicial de agua subterránea (mm)
- QRCFSANT: Caudal en el río el día antes al de inicio de la corrida (m³/s).

b)- Entradas Continuas:

- RO () : Caudal medio mensual observado (m³/s). (Se entran 12 valores cada vez).
- BWPET (): Evaporación de tina "A" total mensual (mm) (se leen 12 valores cada vez de DATA).
- RF (): Lluvia diaria (mm) (se leen entre 28 y 31 valores cada vez de DATA).

II. 3 SALIDAS.

En el proceso de la simulación se producen salidas iniciales, continuas y finales.

a)- Salidas iniciales. Se imprimen las fechas que identifican el inicio y término de la corrida, los parámetros que describen las características hidrológicas de la cuenca y los valores iniciales de los almacenamientos.

b)- Salidas continuas. Despues de cada año procesado se imprimen los valores al final de cada mes de las variables que definen el estado del sistema, los totales mensuales y el total anual de las láminas asignadas a los diferentes procesos del ciclo hidrológico y los caudales medios diarios simulados y observados (si existen) y sus medias mensuales y anual. Las variables que se considera más importantes identificar son:

- ESCT () : Escurrimiento total del mes.
- ESCI () : Escurrimiento de áreas impermeables del mes.
- ESCB () : Escurrimiento base del mes.
- ESCS () : Escurrimiento superficial del mes.
- PREC () : Precipitación del mes.
- ETPO () : Evapotranspiración potencial del mes.

- ETRE () : Evapotranspiración real del mes.
- UZF () : Lámina almacenada en la zona superior al final del mes.
- BZF () : Lámina almacenada en la zona inferior al final del mes.
- GWF () : Lámina almacenada en agua subterránea al final del mes.
- BAL () : Balance del mes.

c)- Salidas finales. Se imprimen los valores que definen la curva de duración de caudales medios diarios simulados para el período de la corrida.
